initially employed to study the parasite biology and its interactions with the host cells. Later their obvious advantages led to extensive use in antiparasitic drug screening based on flow cytometry and fluorimetric, high-throughput screening and in situ imaging. Reporter genes which have found applications in parasitic disease research and drug screening include GFP,

Reporter Genes in Parasites, Fig. 1 Types of reporter genes and their applications

enhanced GFP (EGFP), red fluorescent protein (RFP), yellow fluorescent protein (YFP), CAT, β -gal, firefly luciferase, and β -lac (Serenio et al. 2007; Dube et al. 2009; Singh et al. 2009). Among parasites, main applications of reporter genes are for protozoan parasites because of their unicellular structure, uniform distribution of reporter gene product, and easy and efficient detection. Reporter gene can be expressed episomally (gene inserted in a vector which expressed under selective drug pressure) or as integrating expression constructs (where gene is inserted into the host gene locus, preferably 18S ribosomal gene promoter by homologous recombination).

Green Fluorescent Protein (GFP) and Other Fluorescent Proteins

GFP is a small single polypeptide protein isolated from jellyfish *Aequorea victoria* having 238 amino acids and MW 28 kDa. GFP is intrinsically fluorescent without any substrate and fluoresce green at Ex. 395 nm and Em. 509 nm. Its bioluminescence is due to Ser-Tyr-Gly cyclization within its primary amino acid sequence (Fumarola et al. 2004; Serenio et al. 2007; Dube et al. 2009).

GFP allows easy imaging and nondestructive and repeated quantification using fluorescence microscope, fluorescent-activated cell sorter (FACS), or microplate fluorimeter. Protein engineering-mediated mutations offered new and superior variants of GFP with intense fluorescence and comparative detection. These mutants include enhanced green fluorescent protein (EGFP), yellow fluorescent protein (YFP), red fluorescent protein (RFP), and cyan fluorescent protein (CFP; reviewed elsewhere by Dube et al. 2009; Kremers et al. 2011).

GFP expression in protozoan parasites was first achieved through episomal vector, and later this gene was integrated into the parasite genome to achieve stable and enhanced expression. Serenio et al. (2007) and Dube et al. (2009) have extensively reviewed the parasite species in GFP, and its variants are expressed and utilized for drug screening, in vivo imaging, parasite localization, and infection kinetics. In the case of *Leishmania*, transfectant parasites representing old world species (*L. donovani*, *L. major*, *L. infantum*) and new world species (*L. amazonensis*, *L. mexicana*) have been generated and successfully applied for in vitro drug screening against promastigotes, ex vivo screening against amastigotes, and in vivo drug efficacy testing in mice and hamster

model (Fumarola et al. 2004; Sereno et al. 2007; Peters et al. 2008; Beattie et al. 2008; Singh et al. 2009; Dube et al. 2009; Pulido et al. 2012; Forestier 2013). GFP has also been applied extensively to investigate the in vivo disease progression and drug screening against *Plasmodium* and *Trypanosoma*. Since malaria parasite completes its life cycle in mosquito and human, different life stages were transfected and employed successfully to track their fate and progression in respective host (Dube et al. 2009; Adjalley et al. 2011; Vaughan et al. 2012; McLatchie et al. 2013; Miller et al. 2013). Fluorescent proteins proved equally beneficial in the case of *Trypanosoma* (DaRocha et al. 2004; Dube et al. 2009; Goyard et al. 2014), *Giardia lamblia* (Liu et al. 2005), *Cryptosporidium parvum* (Li et al. 2009), and *Trichomonas vaginalis* (Li et al. 2012). These proteins facilitated in vivo imaging of tissues infected with transfected parasites and provided extensive information on fate of parasite inside the host with or without anti-trypanosomal drugs. Peters et al. (2008) utilized RFP-expressing strain of *L. major* to visualize neutrophilic infiltration at sites of sand fly bites using dynamic intravital microscopy and flow cytometry. Fluorescent assays based on flow cytometry, microplate fluorimeter, and high-throughput screening platforms resulted in identification of several promising lead molecules from natural (plant and marine) and synthetic compound libraries (Dube et al. 2009; Singh et al. 2009). Rocha et al. (2013) developed red fluorescent protein expressing *L. amazonensis* for in vitro and semi-in vivo drug screening using flow cytometry, macrophage infection and fluorimetric assay. Similarly, YFP and RFP have been expressed in *T. cruzi*, *T. rangeli*, and *Toxoplasma gondii* (reviewed by Dube et al. 2009) (Fig. 2).

GFP and other fluorescent proteins as reporter gene in antiparasitic screening assays offer significant edge over conventional assays and other reporter genes due to procedural and technical advantages. These proteins exhibit homogeneous intracellular expression, superior sensibility, specificity, and amenability to live imaging. Several species of *Leishmania*, *Plasmodium*, *Trypanosoma*, and *Toxoplasma* have

been generated which express fluorescent proteins constitutively from gene which is stably integrated at 18S RNA gene locus of host chromosome. These stable transfectants offered significant boost to high-throughput screening and intra-macrophage drug screening (Sereno et al. 2007; Dube et al. 2009; Pulido et al. 2012).

β-Galactosidase (β-Gal)

It is a protein encoded by bacterial *lacZ* gene which can be easily detected by colorimetric or fluorescence assays (Table 1). Due to ease of detection and substrate (X-gal, CPRG) availability, β-gal has found applications for *Plasmodium*, *Leishmania*, *Toxoplasma*, and *Trypanosoma* species (reviewed by Dube et al. 2009). However, owing to the large size (116 kDa) of expressed protein and endogenous expression within macrophages and most of mammalian cell lines, its applications remained limited for parasite research.

β-Lactamase (β-Lac)

Lack of β-lac in eukaryotic cells makes it an attractive reporter gene for parasites (Table 1). This gene encodes a family of catalytic enzymes in bacteria that cleave antibiotics such as penicillins and cephalosporins. This reporter gene system has advantages of being amenable to multiple assay formats (cytosolic, membrane-associated, or secreted forms) as well as availability of numerous substrates for colorimetric/fluorescence detection. β-lac has been successfully expressed in protozoan parasites, *Leishmania* and *Toxoplasma*, and subjected to in vitro drug screening (reviewed by Dube et al. 2009).

Luciferase (Luc)

It is an enzyme synthesized by firefly (*Photinus pyralis*), sea pansy (*Renilla reniformis*), marine copepod (*Metridia longa*), and some bacteria

Reporter Genes in Parasites, Fig. 2 Expression of reporter genes in different parasites and its detection by fluorescence and bioluminescence techniques. (1a, b) Expression of GFP in *Leishmania donovani* promastigotes and intracellular amastigotes; (2a, b) Expression of RFP in *Trypanosoma cruzi* epimastigotes; (3) Expression of

chimeric GFP in *Plasmodium falciparum*; (4) In vivo imaging of luciferase- expressing *L. infantum chagasi* in mice; (5) In vivo imaging of EGFP-expressing *L. major* in mice footpad (Images kind courtesy: Fig. 1 and 2. Dube et al. 2009; Fig. 3. Kadekoppala et al. 2000; Fig. 4. Thalhofer et al. 2010; Fig. 5. Bolhassani et al. 2011)

(*Photobacterium* spp.). Firefly luciferase, the most commonly used form, is a euglobulin protein (MW 61 kDa) that catalyzes the oxygenation of luciferin to oxyluciferin using ATP, Mg^{2+} , and O_2 with emission of short-lived flash of light by the process of bioluminescence. Luciferase produces an initial burst of light upon addition of luciferin to the cell lysates that diminishes within 15 s to a low level of luminescence. Several species of *Leishmania*, *Plasmodium*, *Trypanosoma*, *Toxoplasma*, and *Entamoeba* expressing luciferase (episomal or stable integration) have been developed and evaluated for in vitro, ex vivo, and

in vivo drug screening, as well as for parasite imaging within animal host by invasive and non-invasive methods (Sereno et al. 2007; Dube et al. 2009; Close et al. 2011; McLatie et al. 2013; Miller et al. 2013; Reimao et al. 2013).

This system has been adapted to evaluate potential antiparasitic compounds (natural products and synthetic compounds) in 96-well microplate format. The most notable feature of luciferase is its suitability to perform live non-invasive imaging of bioluminescent parasites in animal models using CCD camera. Luciferase-transfected *L. Infantum chagasi* and

L. mexicana were imaged multiple times following intradermal or intravenous infection. Additionally, quantitative measurements were also performed over a long duration of time postinfection. However, parasites detection was made only in cutaneous locations but not in deeper visceral organs (Thalhofer et al. 2010). Similar in vivo imaging studies were also performed by Vaughan et al. (2012), Reimao et al. (2013), Miller et al. (2013), and McLatie et al. (2013). In spite of being rapid, highly sensitive, and reproducible, the luciferase based assays require the use of costly substrates and the lysis of cells at the end of the experiments thus making repeated measurements unfeasible.

Dual-Reporter Gene System

Dual-reporter gene system refers to the simultaneous expression and measurement of two entirely different reporter enzymes within a single in vitro system or live animal host. While one of the reporter genes directly correlates with the effect of specific experimental variable, the second reporter serves as an internal control. These systems are particularly effective in minimizing data variability which resulted due to transfection efficiency, cell lysis efficiency, and detection efficiency. Some examples of dual-reporter systems include firefly luciferase + Renilla luciferase and luciferase + GFP (Vaughan et al. 2012). This research group has created transgenic *P. falciparum* NF54 parasite that expresses both GFP and luciferase together throughout the life cycle. These novel parasites were easily and accurately measured at all life cycle stages (midgut oocyst, salivary gland sporozoites, and liver stages). Similarly, Adjalley et al. (2011) generated *P. falciparum* that expressed stably integrated gametocyte-specific GFP-luciferase reporters which facilitated accurate and sensitive monitoring of parasite sexual development throughout the five stages of gametocytogenesis and also the determination of gametocytocidal activity of antimalarial drugs.

Applications of Reporter Genes for Antiparasite Drug Discovery

Episomal- and stable-transfected *Leishmania*, *Plasmodium*, *Trypanosoma*, *Toxoplasma*, and other parasites were successfully adapted to drug screening assay against culture stage (in vitro), intracellular stage (ex vivo), and intra-tissue stages (reviewed elsewhere by Sereno et al. 2007; Dube et al. 2009). For in vitro screening assays, microplate system, flow cytometry, and microplate fluorimetric methods are commonly employed. These studies are summarized in Tables 2 and 3.

Clinical Relevance

Reporter genes have proved very useful in elucidating the responses of clinical isolates of *L. donovani* from patients which were unresponsive toward sodium stibogluconate. GFP- based reporter gene assays established excellent correlation with clinical and in vitro drug responses (Singh et al. 2009). Further, expression of genes involved in drug resistance, abnormal membrane transport, and apoptosis-related processes can be determined with reporter gene technology.

Conclusions

From the early 1990s to the present date, reporter gene technology has witnessed enormous advancements and achieved multifold applications in parasite gene functions, host-parasite biology, and drug discovery. These developments have revolutionized in vitro, intra-macrophage, and in vivo drug discovery with the emergence of several novel lead compounds against parasitic diseases which are facing critical situation due to lack of vaccine and effective chemotherapeutic interventions. Further, it becomes possible to measure real-time in vivo imaging of animal hosts to determine drug/vaccine efficacy and parasite localization. However, there is still a scope for refinement of existing reporter gene

Dr. Nasib Singh completed his MSc degree in Microbiology with distinction (Gold Medal) from Kurukshetra University in 2001. He then joined doctoral program at Central Drug Research Institute, Lucknow, and worked on the development of in vitro and in vivo drug screening models against visceral

leishmaniasis, a neglected tropical infectious disease. In 2008, Dr. Singh moved to The University of Texas Medical Branch (Texas, USA) for postdoctoral fellowship and worked on molecular and immunological aspects of host-pathogens interactions during *Leishmania* and *Francisella* infection. During 2011–2013, Dr. Singh was engaged in deciphering the rumen microbial diversity in ruminants and the impact of plant/microbe-based feed additives on methanogenesis and utilization of poor quality fibrous feeds at Nutrition Biotechnology Division of National Dairy Research Institute, Karnal. He then worked in an academic position at Lovely Professional University, Punjab from 2013–2015. Currently, he is working in the Department of Biotechnology at Eternal University, Himachal Pradesh. Dr. Singh made several significant scientific contributions to the areas related to antileishmanial drug development using transgenic *Leishmania* parasites, immunomodulation, host-pathogen biology, and rumen microbial ecology. These studies have resulted in more than 25 publications in peer-reviewed journals and several book chapters. He is also an editorial board member of

journal Parasitology Research. He is a recipient of Junior and Senior Research Fellowships from CSIR, New Delhi. He has also coedited a book entitled *Livestock Greenhouse Gases: Emission and Options for Mitigation*.

Reproduction Strategies

In general, parasites must develop means for the mass production of offspring, a common method being asexual divisions of individuals. Another very common means of increasing the biotic potential is the production of numerous eggs after sexual processes, which also enhances the chance of a favorable genetic recombination (► [Chromosomes](#), ► [Nuclear Division](#)). There are basic differences between the modes of reproduction of protozoan and metazoan parasites (► [Protozoa/Reproduction](#)).

RESA

Ring-infected erythrocyte antigen of *Plasmodium* merozoites.

Reserve Granules

All parasitic ► [Protozoa](#) have various types of ► [vacuoles](#), the largest of which are the food vacuoles (► [Endocytosis](#), Fig. 1A, B, ► [Merozoite](#), Fig. 1); these disintegrate during digestion. Vacuoles that serve as storage elements contain crystalloid proteins (Fig. 1c, ► [Cyst Wall](#), Fig. 2B), lipids, or carbohydrates (Fig. 1b, ► [Surface Coat](#), Fig. 1A). Lipid-containing vacuoles appear slightly gray in electron micrographs and are present mainly in resting stages such as cysts. Large amounts of protein are found in the ► [refractile bodies](#) of sporozoan sporozoites (► [Cyst Wall](#), Fig. 2B) and in haemosporidian ookinetes. Carbohydrates are generally stored in the form of granules of glycogen or amylopectin (► [Surface Coat](#), Fig. 1A). Amylopectin-

Reserve Granules,

(a) *Sarcocystis ovifelis*; cyst ► **merozoite** in cross section; using the thallium ethylate method of Mentrö, DNA and RNA components become visible ($\times 70,000$). (b) *Besnoitia jellisoni*; motile stages of eimeridian ► **Sporozoa** contain amylopectin granules, which are stained here (in cyst merozoites) by the Thiöry silver-proteinate method. Note the ► **opisthaptor** of polysaccharides on the ► **pellicle** (PE) ($\times 65,000$). (c) In schizonts of ► *Isospora* spp. and in ookinetes and oocysts of ► *Plasmodium* spp. lipoproteins appear in a crystalline pattern (normal contrast) ($\times 45,000$) (A amylopectin granules, CH condensed ► **chromosomes**, CR crystalline proteins, ER endoplasmic reticulum, MI mitochondrion, ML multilaminar body, MN ► **micronemes**, N nucleus, NM nuclear membrane, OM outer limiting membrane (of the ► **schizont**), PE pellicle, PV ► **parasitophorous vacuole**, RI ribosomes)

containing granules appear as brilliant white areas in the electron micrographs of ► **gregarines**, coccidians, and some endoparasitic ciliates (Fig. 1b, ► **Cyst Wall**, Fig. 2B). These granules are scattered throughout the ► **cytoplasm** of sporozoans of all developmental stages except ► **microgametes**, and are particularly numerous in the cytoplasm of macrogametes and oocysts (► **Cyst Wall**, Figs. 1A, 2B, ► **Macrogamete**, Fig. 1). Glycogen (► **Surface Coat**, Fig. 1A) is

present as small randomly distributed granules in the cytoplasm of ► *Tritrichomonas foetus* and as a large mass in the cytoplasm near the nucleus in *Entamoeba* or *Iodamoeba* cysts as well as in the host cells.

In all helminths glycogen is the predominant storage material. While in the ectoparasitic ► *Monogenea* glycogen represents only 1 % of the dry body weight, it may increase to 30–36 % in ► **tapeworms** and up to 30 % in male

schistosomes. In female schistosomes, however, only 3.5 % of the dry weight is accounted for by glycogen. The glycogen is degraded during ► [glycolysis](#) and used during many processes. Besides glycogen many lipid droplets and protein inclusions are stored in the cells of the helminths (► [Tegumental Disks](#), ► [Calcareous Corpuscles](#)). The lipids reach up to 16 % of the dry weight in tapeworms (e.g., ► [Taenia solium](#), [► [Moniezia expansa](#)]).

Reserve Pool

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Some larvae 3 of *Oesophagostomum* species enter the wall of the colon of their hosts; however, they stop further development until the other worms, which had developed directly into maturity, have left the intestine. Thus these “late comers” guarantee a longer-lasting infection.

Reservoir Host

Organism in which a parasite that is pathogenic for some other species lives and multiplies without doing serious damage to its host.

Reservosomes

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Intracellular organelles described in ► [Trypanosoma cruzi](#). They are probably glyoxysomes, which process lipids for energy in many protozoans.

Residual Body

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This term describes broad-spectrum products, which remain as rests of a formation of motile stages (e.g., schizogonic rests after disruption of produced merozoites) in ► [Coccidia](#). In intra-erythrocytic schizonts of ► [Plasmodium](#) species, the remnants of the formation of the merozoites contain crystalline components, which consist in part of the iron components of the hemoglobin of the red blood cell.

Residual Effect

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This term describes the duration of the efficacy of an acaricidal or insecticidal compound.

Resilience

This term describes the ability of an infected animal to withstand the negative pathophysiological consequences of a penetrated parasite.

Resistance

Resistance is the ability of an organism not to get infected by certain parasites.

One may wonder why hosts, especially the ones which possess a sophisticated immune system, rarely get totally rid of their parasites under natural conditions. There are 2 answers to this apparent paradox. The first is that parasites and hosts are engaged in arms races (► [Virulence/Evolutionary Aspects](#), ► [Coevolution](#)) and that parasites, thanks to a high degree of genetic variation and to short generation times, can rapidly select counter-responses to the weapons selected by the hosts. The second is that there exists a cost of resistance.

A demonstration of the cost of resistance, among others, was indirectly made by a study on the mechanisms by which antelopes fight against their ectoparasites (► [ticks](#) principally). McKenzie and Weber filled with cement the interdental spaces of one side of the mandible of a series of impalas. Filling the spaces prevented normal grooming in such a way that the antelopes could still remove their ectoparasites with their dental apparatus on one side of the body but not on the opposite side. The result was that, after 4 weeks in the wild, the number of ticks was

approximately 10 times higher on the “filled side” (up to 15,000 thousands ticks were counted per half-antelope) than on the normal side (Fig. 1). An interesting feature is that, even on the “normal side,” not all the ticks were ever removed. There are several possible explanations to that, including the fact that new parasites attach continuously to the skin. But it is also most likely that an individual which would try to remove all or nearly all its parasites, would be constrained to spend less time to forage and would be less attentive to detect predators: the cost of resistance would then outweigh its benefits.

Resistance Against Drugs

Bayer HealthCare AG, Division Animal Health, Leverkusen, Germany

Genetically transmitted decreased sensitivity against drugs. ► [Resistance](#), ► [Drug](#) and ► [Chemotherapy](#).

Resistance, Fig. 1 Ectoparasites of antelopes and cost of resistance. An experiment in the field shows that, when antelopes are prevented from normal grooming, the number of ectoparasites is increased in 4 weeks by a factor of 10 or more. Filled = side of the body where interdental spaces of the lower jaw were filled with cement; normal = side of the body where interdental spaces were left unfilled; #1, #2, etc. = different individuals (Original, data from McKenzie and Weber)

Resistance Encoding Genes

In *Plasmodium falciparum* drug-resistant strains the following genes had changed, when treatment was done with:

- Artemisinin: *atp6*, *mdr1*
- Atovaquone: *cytb*
- Chloroquine: *crt*, *mdr1*
- Chlorproguanil: *dhfr*
- Dapsone: *dhps*
- Doxycycline: *mt protein synthesis*
- Halofantrine: *mdr1*
- Lumefantrine: *mdr1*
- Proguanil: *dhfr*
- Sulfadoxine: *dhps*
- Tetracycline: *mt protein synthesis*
- Trimethoprim: *dhfr*

Resistance Mapping in Malaria Treatment

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Malaria treatment is always characterized by continuous introduction of medicaments in an endangered population. This introduces resistance of different degrees against the various chemical compounds. Therefore activities are needed to have an actual knowledge on the degrees of resistances. The method of resistance mapping is very useful to become aware of the actual status of medicament resistance in a given region.

Resistance Types of Insects

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The WHO defined several types of resistances, which are commonly developed, when insects come in contact with major insecticides. In general insecticide resistance is described as the ability of single insect individuals to withstand the effects of an insecticidal compound by avoiding toxic effects by means of development of certain mutations and/or by effects of natural selection (i.e., only those individuals persist, which survive a certain dosage of an insecticide). The following types of insecticide resistance are rather common:

1. Behavioral resistance

This type is based on any modification in the behavior of a given (individual) insect that helps to avoid the contact to an insecticide.

2. Cross resistance

This type occurs when an insect is able to avoid the activity of at least two insecticides, which may even belong to different classes of insecticides.

3. Cuticular resistance

This type is based on special features of the cuticle and/or intestinal lining systems that prevent or slow down the absorption or penetration of a peculiar insecticide.

4. Metabolic resistance

This type is due to an overexpression of enzymes by the insect, which are able to detoxify or sequester insecticides and/or amino acid substitutions within these enzymes that alter the affinity of the enzyme for the insecticide.

5. Multiple resistance

This type occurs if insects express several types of resistances at the same time, so that they are practically no more affected.

6. Operational field resistance

This phenomenon occurs when many insecticides were repeatedly used after failure of efficacy in the field.

7. Phenotypic resistance

This type occurs if an insect expresses a resistance gene that offers ongoing protection.

8. Target site resistance

This type brings changes in the sensitivity of a given insecticide target due to non-silent point mutations.

In general several of the above-described reactions may occur at the same time or in close time-neighborhood.

Respiratory System Diseases, Animals

General Information

A wide variety of clinical signs and pathological lesions may result from invasion of the respiratory system by parasites. The severity of the clinical manifestations depends largely on the number of parasites present and on which part of the tract they normally invade. It is also determined by individual variations between hosts in the anatomical and physiological features of the respiratory tract, or in the nature of the response to infection. As for many other parasitic diseases, the parasites

that cause respiratory problems do not all live in the respiratory system as adults; some (e.g., ► [Ascaris](#), [Ancylostoma](#), ► [Strongyloides](#)) pass through the lungs in the normal course of their migration whereas others may penetrate the system by error (e.g., *Fasciola*). Finally, parasites residing primarily in other systems may cause syndromes in which respiratory difficulties are one of the foremost presenting signs (e.g., ► [Dirofilaria immitis](#)).

Manifestations and Pathophysiology

As with other parasitic diseases the clinical signs resulting from infection of the respiratory tract may vary from mild to very severe. The principal clinical manifestations of respiratory dysfunction are hyperpnea, tachypnea, dyspnea, respiratory noises, and nasal discharge. Table 1 provides a list of the different parts of the respiratory tract and of the clinical signs which may be observed when they are affected.

Parasites living in the nasal passages and/or the sinuses induce inflammatory reactions of the mucosa. Rhinitis and sinusitis start as catarrhal inflammations characterized by a nasal discharge which is serous initially, but rapidly becomes mucoid and purulent. Sneezing is also a characteristic (Fig. 1). Wheezing and stertor may be present when both nostrils are partially

Respiratory System Diseases, Animals, Table 1 Clinical signs associated with specific anatomic involvement of the respiratory tract (according to Vercruysse and De Bont)

Anatomic area	Clinical signs
Nasal cavity	Nasal discharge, snorting, sneezing, nasal rubbing
Sinuses	Nasal discharge
Larynx	Dyspnea, coughing
Trachea	Harsh resonant cough, dyspnea
Bronchi or bronchioles	Coughing, dyspnea
Alveoli	Cough when associated with bronchial pathology, hyperpnea, dyspnea

Respiratory System Diseases, Animals, Fig. 1 Parasites causing sneezing and coughing

Respiratory System Diseases, Animals, Fig. 2 Parasites causing dyspnea at rest

obstructed. The irritation may cause the animal to shake its head, or rub its nose against the ground or its front legs. Inflammation of the larynx, trachea, and bronchi are characterized by cough,

noisy inspiration, and some degree of inspiratory dyspnea (Figs. 1 and 2).

► **Pneumonia** is an inflammation of the lung, usually accompanied by inflammation of the

bronchioles, and sometimes by pleuritis (pleuropneumonia). It is manifested clinically by an increase in respiratory rate, cough, dyspnea, and sometimes nasal discharge (Figs. 1 and 2). The most important parasites causing bronchiolitis and alveolitis are helminths belonging to the Dictyocaulinae and Metastrongylidae. The reaction to the presence of eggs, larvae, or adults is comparable to the one induced by foreign bodies, with accumulation of masses of eosinophils, macrophages, and giant cells. The lesions may cause the dysfunction of large masses of lung tissue. Emphysema commonly accompanies pneumonia, particularly in cattle. It is presumed to be caused by a combination of blockage of bronchioles and violent coughing so that air retained in the alveoli exerts enough pressure to cause a rupture of the alveolar walls.

The larvae of several intestinal ► **nematodes** (e.g., ascarids, ► **hookworms** and *Strongyloides*) normally migrate through the lungs. Once in the bronchioles, they are coughed up and swallowed, to eventually reach the small intestine where they mature. In the lungs, they cause a transitory eosinophilic alveolitis and bronchiolitis. Although the pathogenesis of the lesions is attributable mainly to the physical damage caused by larvae, there is also evidence of hypersensitivity in the modulation of infection.

Most parasitic infections of the respiratory tract are associated with peripheral ► **eosinophilia**.

Treatment

► **Chemotherapy**, ► **Drugs**.

Respiratory System Diseases, Horses, Swine, Carnivores

The common clinical signs and pathology of parasitic infections of the respiratory system of horses, swine, and carnivores are summarized in Table 1.

Nasal Cavity and Sinuses

► *Linguatula serrata* is a pentastomid which infects the nasal passages of dogs and rarely horse, goat and sheep. The adult parasites are up to 12 cm long and lie on the surface of the nasal mucosa. No symptoms of nasal irritation are apparent except for occasional sneezing, and sometimes epistaxis.

The mite ► *Pneumonyssus* (*Pneumonyssoides*) *caninum* is occasionally found in the nasal passages and sinuses of dogs. It is usually an incidental finding not associated with clinical signs or the development of lesions. However, there are reports of the ► **mites** causing mild rhinitis, sinusitis, and even bronchitis. Clinical signs include chronic sneezing, head shaking, epistaxis, and impaired scenting ability.

A naso-pharyngeal myiasis of horses, with similar clinical symptoms as ► *Oestrus ovis* is caused by ► *Rhinoestrus purpureus*, the ► **Russian gadfly**. ► **Leeches** such as *Dinobdella ferox* commonly enter the nasal cavities of domestic animals, mainly in southern Asia. They suck blood, generally induce inflammation, and may impede breathing.

Larynx and Trachea

Capillaria aerophila (*Eucoleus aerophilus*) is found mainly in the trachea and the nasal cavity of dogs and cats. Mild infestations are asymptomatic and provoke a mild catarrhal inflammation with nasal discharge and a mild cough. In heavy infestations a persistent dry cough and intermittent dyspnea may be observed.

► *Filaroides* (*Oslerus*) *osleri* is an ► **ovoviviparous**, filiform worm parasitizing the dog and related species. The worms cause submucosal ► **nodules** of up to 10 mm in diameter in the region of the tracheal bifurcation. The clinical symptoms are proportional to the severity of infection and the number and size of the tumors. The most frequently recorded symptom is a sporadic but persistent nonproductive cough. The most severe clinical cases, which usually occur

Respiratory System Diseases, Horses, Swine, Carnivores, Table 1 Parasites affecting the respiratory system of horses, swine, dogs (according to Vercruysse and De Bont)

Parasite	Type	Host	Location	Clinical presentation	Principal lesions
Protozoa					
<i>Pneumocystis carinii</i>	1	Dog	Alveoli	Clinical signs when impairment of host resistance: dyspnea, tachypnea, cough, cyanosis	Interstitial pneumonia with massive mononuclear cell infiltration
<i>Sarcocystis</i> spp.	3	Pig (intermediate)	Vascular endothelium	Anorexia, fever, weight loss, anaemia, and dyspnea	Lungs: mild interstitial pneumonitis and vasculitis
<i>Toxoplasma gondii</i>	1	Pig1, carnivores	Alveoli	Anorexia, fever, and lethargy accompanied by dyspnea	Lungs: focal areas of coagulation necrosis, adjacent to and involving small vessels and bronchioles
Trematoda					
<i>Paragonimus</i> spp.	1	Cat, dog	Lung parenchyma	Mild intermittent coughing, expiratory wheezing, and on occasion, acute dyspnea	Cystic lesions, eosinophilic granulomatous pneumonia
Nematoda					
Rhabditida					
<i>Strongyloides</i> spp.	3	Pig, dog	Small intestine, larvae migrate through lungs	Light coughing	Transitory eosinophilic alveolitis and bronchiolitis
Strongylida					
<i>Aelurostrongylus abstrusus</i>	1	Cat	Terminal bronchioles	Occasionally coughing, sneezing, oculo-nasal discharge	Light bronchiolitis, hypertrophy of the arterial and arteriolar smooth muscles
<i>Ancylostoma</i> spp. and other hookworms	3	Carnivores	Small intestine, larvae migrate through lungs	Soft cough	Petechial hemorrhages on the lungs with transitory alveolitis and bronchiolitis
<i>Angiostrongylus vasorum</i>	3	Dog	Pulmonary artery and rarely in right ventricle	Dyspnea and dead of cardiac insufficiency	Pulmonary oedema, granulomatous interstitial pneumonia
<i>Crenosoma vulpis</i>	1	Dog, cat	Bronchi, occasionally trachea	Coughing and dyspnea	Catarrhal eosinophilic bronchitis
<i>Dictyocaulus arnfieldi</i>	1	Donkey, horse	Bronchi	Clinical signs mainly in horses: coughing, hyperpnea and nasal discharge	Bronchitis, bronchiolitis, pneumonitis
<i>Filaroides</i> spp.	1	Dog	Alveoli and bronchioles	Usually no clinical signs, respiratory distress has been noted	Foci of granulomatous interstitial pneumonia
<i>Filaroides osleri</i>	1	Dog	Tracheobronchial bifurcation	Nonproductive cough, dyspnea, exercise intolerance, cyanosis	Submucosal, firm nodules

(continued)

Respiratory System Diseases, Horses, Swine, Carnivores, Table 1 (continued)

Parasite	Type	Host	Location	Clinical presentation	Principal lesions
<i>Metastrongylus</i> spp.	1	Pig	Bronchioles, small bronchi	Husky cough, slight dyspnea	Bronchitis, bronchiolitis, pneumonitis
Spirurida					
<i>Dirofilaria immitis</i>	3	Dog, cat	Right heart ventricle, the pulmonary artery	Deep, soft, cough, hemoptysis, dyspnea	Endarteritis, secondary pulmonary parenchymal lesions
Ascaridida					
<i>Ascaris suum</i>	2	Pig	Small intestine, transit of larvae through lung parenchyma	Coughing	Transitory eosinophilic alveolitis and bronchiolitis, lesions more marked in repeated infections
<i>Parascaris equorum</i>	2	Horse	Small intestine, transit of larvae through lung parenchyma	Coughing and nasal discharge	Transitory eosinophilic bronchitis and bronchiolitis
<i>Toxocara canis</i>	2	Dog	Small intestine, transit of larvae through lung parenchyma	Coughing, in young dogs dyspnea, death	Transitory multifocal interstitial pneumonitis
Enoplida					
<i>Capillaria aereophila</i>	1	Dog, cat	Nasal cavity, trachea	Nasal discharge, mild cough, in heavy infestations dyspnea	Mild catarrhal rhinitis and tracheitis
Arthropoda					
Acaridia					
<i>Pneumonyssus caninum</i>	1	Dog	Nasal passages, sinuses	Occasionally sneezing	Mild rhinitis, sinusitis
Diptera					
<i>Rhinoestrus purpureus</i>	3	Horse	Nasal passages, sinuses, pharynx	Nasal discharge, sneezing death (larval aspiration)	Rhinitis, sinusitis, pharyngitis
Pentastomida					
<i>Linguatula serrata</i>	1	Dog, more rarely in horse	Nasal cavities, occasionally paranasal sinuses	Occasionally sneezing with mucous discharge	Catarrhal rhinitis

1 A primary parasite of the respiratory system. 2 Affects the lungs through normal migration or proliferation. 3 Parasites of another organ system that produces respiratory symptoms

in pups under 1 year of age, show persistent coughing, respiratory distress and emaciation, with up to 75 % mortality rates in affected litters.

migration, causing various degrees of damage according to the nature and intensity of the host-parasite interaction.

Lower Respiratory Tract

As for ruminants, some species such as the lung-worms use the lower air passages and more rarely the lung ► **parenchyma** as final habitat. Other species just pass through the lungs during their

Protozoa

► *Toxoplasma gondii* can infect a wide variety of cell types in nearly all warm-blooded animals, and the clinical picture in a particular host species depends on the particular involvement of any one or more of these organs. In dogs and cats, involvement of the lungs is a common feature. In

dogs, clinical toxoplasmosis is most frequent in puppies, and is often complicated by the simultaneous manifestations of distemper. The clinical syndrome is variable in course but ► [anorexia](#), fever, and lethargy accompanied by dyspnea are the essential features. Proliferation of the organism in the lungs leads to focal areas of coagulation necrosis adjacent to and involving small vessels and bronchioles and exudation of fibrin.

► *Pneumocystis carinii* is a protist of uncertain taxonomy which inhabits the pulmonary alveoli of dogs, horses, goats, pigs, and humans, and which may give rise to severe respiratory distress in hosts who suffer from immunodeficiency. The onset of pneumocystosis can be acute or insidious. Signs of dyspnea, tachypnea, cough, periodic cyanosis, and ► [weight loss](#) were noted in otherwise alert animals. The disease may take a progressive course and death can occur in a few weeks if the patient is not treated.

Nematodes

In contrast with horses, donkeys are only slightly affected by even heavy infections with ► *Dictyocaulus arnfieldi*. It has been concluded that donkeys are the natural host of the parasite. Infections in horses are generally nonpatent, but may be associated with clinical signs such as coughing, increased respiratory rate, and nasal discharge.

Metastrongylus spp. are transmitted by earthworms and thus only occur in wild boars and occasionally in domestic pigs when kept on pasture. There are three important species of *Metastrongylus*: *M. elongatus* (*M. apri*), *M. pudendotectus*, and *M. salmi*. They are all parasitic in the bronchi and bronchioles of pigs. The lesions caused by the parasites resemble those caused by *Dictyocaulus* spp. in ruminants but, generally speaking, with much lighter clinical signs. Infected pigs often develop a husky cough which, if infections are heavy, may get superimposed by often fatal bacterial or viral infections.

Aelurostrongylus abstrusus is a small metastrongyle that develops in the bronchioles of cats and is capable of eliciting extensive bronchiolitis and interstitial ► [pneumonia](#). In clinically-infected cats abnormal respiratory signs with coughing,

sneezing, and some degree of oculo-nasal discharge appear 6–12 weeks after infection. Most cases show little clinical disturbance, because the lesions regress spontaneously as immunity develops.

Crenosoma vulpis, a small metastrongyle, occurs in the bronchi and occasionally the trachea of foxes, dogs, and cats. The adult worms induce a catarrhal eosinophilic bronchitis with heavy coughing and dyspnea.

Filaroides milski and *F. hirchi* live in the alveoli and bronchioles of dogs causing interstitial pneumonia. Clinical signs of infection are rare although respiratory distress and even mortality have been reported.

Paragonimus kellicotti is a digenetic fluke that inhabits fibrous cysts in the lungs of wild carnivores and domestic cats and dogs. *P. westermani* occurs in the lungs and more rarely in the brain and spinal cord of dogs, cats, wild animals, and humans. The clinical signs include mild coughing, expiratory wheezing, and on occasion, acute dyspnea. Pneumothorax may be a rare complication in both dogs and cats. Lesions are mainly due to the adult ► [flukes](#) which are found, usually in pairs, in inflammatory cysts in the pulmonary parenchyma and occasionally the bronchi of predominantly the right caudal lung lobes.

Angiostrongylus vasorum occurs in the pulmonary artery and rarely in the right ventricle of the dog and the fox. They cause a proliferative endarteritis comparable to that induced by ► *Dirofilaria immitis*, but the more severe damage is caused by eggs that lodge in arterioles and capillaries. Together with the larvae they provoke a chronic inflammation in which fibroplasia predominates. The larvae break into the alveoles and migrate in the respiratory passages. Affected animals suffer from dyspnea and may die of heart failure. The fatal outcome is largely attributable to pulmonary ► [edema](#) and pneumonia.

Infection with *D. immitis* in dogs generally gives rise to respiratory involvement. The pneumonitis is caused by granuloma formation around microfilariae trapped in the lung. The clinical signs of heart worm disease are discussed in the section on parasitic vasculitis (► [Cardiovascular System Diseases, Animals](#)). The larvae of several intestinal ► [nematodes](#) pass through the lungs

during the course of their normal migration. Lesions and respiratory signs are most pronounced with the larvae of the ascarids *Ascaris suum*, ► *Parascaris equorum*, and ► *Toxocara* spp. in pigs, horses, and carnivores, respectively. The migration of *P. equorum* larvae through the lungs provokes an inflammatory reaction which may result in mild to severe respiratory distress. Larvae of *T. canis* are often present in the lungs of newborn puppies (after transplacental migration), and heavy infections result in substantial hemorrhage into the alveoli during the first day of life. This may prove fatal. Pulmonary lesions are characterized by granulomas and multifocal interstitial pneumonitis.

Acute respiratory signs (coughing) may appear in young animals a few days after exposure to *Strongyloides westeri* (horses). The respiratory signs caused by migration of ► *hookworms* (dogs) are less pronounced.

Aberrant migrations through the respiratory system of parasites such as *Fasciola* spp. or ► *Spirocera lupi* do not usually cause clinical signs and are only detected post mortem.

Treatment/Therapy

► *Chemotherapy*, ► *Drugs*.

Respiratory System Diseases, Ruminants

The common clinical signs and pathology of parasitic infections of the respiratory system of ruminants are summarized in Table 1.

Nasal Cavity and Sinuses

The larvae of a number of flies of the family Oestridae are parasites of nasal cavities and sinuses of ruminants. The most ubiquitous is the nasal ► *botfly* of sheep and goats, ► *Oestrus ovis*. The flies cause great stress when they attack the sheep to deposit larvae near the nostrils of the host, a process which significantly interferes with grazing

and rumination. The larvae which develop in the nasal cavities may get up to 3 cm in length and cause severe discomfort, partly because of the damage caused by the oral hooks and cuticular spines of the larvae, but also because of hypersensitivity phenomena. Nasal discharge and sneezing are common features in affected sheep, with caked dust obstructing the nostrils. Head shaking and nose rubbing may sometimes be seen. Extension to the cranial cavity via the ethmoid causes nervous symptoms and is usually fatal, but is also very rare.

Schistosoma nasale lives in the nasal veins of a variety of domesticated animals on the Indian subcontinent, including cattle, water buffalo, sheep, goat, and rarely horse. The lesions which are granulomatous in nature are caused by the passage of eggs through the wall of the nasal cavity. The condition is associated with cauliflower-like growths on the nasal mucosa causing partial obstruction of the cavity and snoring sounds when breathing. The lesions tend to get more severe in older animals and may become very spectacular in cattle, leading to “► *snoring disease*”.

► *Leeches* such as *Dinobdella ferox* commonly enter the nasal cavities of domestic animals, mainly in southern Asia. They suck blood, generally induce inflammation, and may impede breathing.

Besnoitia besnoiti occurs in cattle in Southern Europe, Africa and Southeast Asia. The parasite multiplies mainly in the skin, but may also alter the mucosa of the upper respiratory tract and the lung may appear edematous. The large cysts are identifiably with the naked eye in the nasal mucosa and at necropsy at the respective predilection sites.

Larynx and Trachea

Mammomonogamus laryngeus occurs in the larynx and the trachea of cattle and humans in Southeast Asia and South America, and *M. nasicola* is found in nasal cavities, trachea, larynx, and bronchi of sheep, goats, and cattle in Africa and South America. In animals there are no apparent symptoms except for a light coughing. There is one record of a fatal infection in sheep believed to be due to a respiratory obstruction initiated by *M. nasicola*.

Respiratory System Diseases, Ruminants, Table 1 Parasites affecting the respiratory system of ruminants (according to Vercruysse and De Bont)

Parasite	Type	Host	Location	Clinical presentation	Principal lesions
Protozoa					
<i>Sarcocystis</i> spp.	2	Ruminants	Vascular endothelium	Anorexia, fever, weight loss, anemia and dyspnea	Lungs: mild interstitial pneumonitis and vasculitis
Trematoda					
<i>Schistosoma nasale</i>	1	Cattle	Nasal mucosal veins	Muco-purulent discharge, dyspnea, snoring	Granulomas in nasal mucosa
Nematoda					
Rhabditida					
<i>Strongyloides</i> spp.	2	Ruminants	Small intestine, larvae migrate through lungs	Light coughing	Transitory eosinophilic alveolitis and bronchiolitis
Strongylida					
Hookworms	2	Ruminants	Small intestine, larvae migrate through lungs	Soft cough	Petechial hemorrhages on the lungs with transitory alveolitis and bronchiolitis
<i>Dictyocaulus filaria</i>	1	Sheep, goat	Small bronchi	Coughing, hyperpnea, and dyspnea	Bronchitis, bronchiolitis, pneumonitis
<i>D. viviparus</i>	1	Cattle	Bronchi, bronchioles	Coughing, hyperpnea, and dyspnea	Bronchitis, bronchiolitis, pneumonitis, pulmonary edema, emphysema
<i>Mammomonogamus</i> spp.	1	Ruminants	Nasal cavities, larynx, trachea, and bronchi	Light coughing	Chronic inflammation with small ulcerations of the mucosa of upper airways
<i>Muellerius capillaris</i>	1	Sheep, goat	Alveoli, pulmonary parenchyma, subpleural tissue	Usually no clinical evidence, sometimes persistent coughing, dyspnea	Bronchiolitis, pneumonitis with nodular lesions
<i>Protostrongylus</i> spp.	1	Sheep, goat	Bronchioles	Usually no definite clinical signs	Bronchiolitis, lobular pneumonitis
Ascaridida					
<i>Toxocara vitulorum</i>	2	Cattle	Small intestine, transit of larvae through lung parenchyma	Coughing	Transitory eosinophilic alveolitis and bronchiolitis, lesions more marked in repeated infections
Arthropoda					
Acaridia					
Diptera					
<i>Oestrus ovis</i>	3	Sheep, goat	Nasal passages, sinuses	Nasal discharge, frequently sneezing, nasal rubbing	Catarrhal rhinitis and sinusitis

1 A primary parasite of the respiratory system. 2 Affects the lungs through normal migration or proliferation. 3 Parasites of another organ system that produces respiratory symptoms

Lower Respiratory Tract

Parasitic infections of the lower respiratory tract of ruminants are very common and important. Some species such as the lungworms use the lower air passages and more rarely the lung ► [parenchyma](#) as final habitat. Other species just pass through the lungs during their migration, causing various degrees of damage according to the nature and intensity of the host–parasite interaction.

Protozoa

Protozoa that are spread across tissues by parasitemia or induce generalized disease may also affect the respiratory system. For instance, lung edema is often observed during babesiosis, mucosal bleedings occur during theileriosis, coughing and dyspnea may develop during toxoplasmosis in small ruminants. ► [Sarcocystis](#) may occasionally cause dyspnea. A multifocal interstitial pneumonitis and vasculitis are responsible for the respiratory signs.

Lungworms

► [Dictyocaulus viviparus](#) is certainly the most important lungworm of cattle in temperate areas. The severity of the clinical signs depends on the susceptibility of the host and on the number of invading larvae. Cattle are most susceptible to infection when they are first exposed to contaminated pastures. Since the occurrence of the primoinfection varies, dictyocaulosis (husk) can be seen in all age classes. In early infections lesions are mainly found in the alveoli, which the larvae penetrate from lymphatics and blood vessels. An eosinophilic exudate accumulates in the alveoli and the terminal bronchioles. Hyperpnea and coughing may become noticeable as soon as 10–14 days after heavy infections. Occasionally, fatal pulmonary ► [edema](#) and emphysema develop at this stage, probably as a result of hypersensitivity reactions. During the patent period (25–55 days after infection), adults reside and lay eggs in the

bronchi where they induce a ► [hyperplasia](#) of the mucosa. Eosinophilic exudate obstructs the lumen of the bronchi, which result in atelectasis of the alveoli distal to the plugs. In addition, eggs aspirated into the alveoli initiate foreign body reactions. The overall consequence of dictyocaulosis is a diffuse consolidation of the lungs. The animals show dyspnea and coughing, with rapid loss of condition. Harsh respiratory sounds with emphysematous crackling can be heard. The post-patent phase of the disease is often one of gradual recovery in that the respiratory rate decreases, weight gain is resumed, and the coughing abates.

D. filaria causes outbreaks of pulmonary nematodosis in sheep and goats in most temperate areas of the world, often with high mortality rates. The pathogenesis and clinical signs appear to be similar to those of ► [D. viviparus](#) infections in cattle.

The Protostrongylidae are common lungworms of sheep and goats. They include *Muellerius capillaris*, *Protostrongylus rufescens*, *P. brevispiculum*, *P. kochi*, and *Cystocaulus ocreatus*. These parasites are of minor pathogenic importance. Infections with ► [Muellerius](#) and *Cystocaulus* are generally associated with small, spherical nodular lesions in the lung tissue, whereas ► [Protostrongylus](#) causes irritation and local inflammatory reactions in the bronchioles resulting in small foci of lobular pneumonitis. Generally animals show no clear symptoms although in the rare heavy infections, and especially with *Protostrongylus* in sheep and *Muellerius* in goats, there may be severe and even fatal disease.

Other Parasites

Larvae of *Ascaris suum* may be responsible for an atypical interstitial ► [pneumonia](#) in grazing cattle. Signs of acute respiratory distress such as severe dyspnea, expiratory grunt, hyperpnea and moist cough appear about 10 days after application of contaminated pig manure as a slurry to the pasture.

Treatment/Therapy

► [Chemotherapy](#), ► [Drugs](#).

Retinochoroiditis

Toxoplasma infections may induce severe eye disease; this retinochoroiditis is a progressive recurring disease in immunosuppressed and immunocompetent patients, which can cause severe morbidity (e.g., yearly about 3,000 congenital infections occur in the USA, 1,500 in Germany).

Retortamonadida

Classification

Order of ► [Mastigophora](#).

General Information

These relatively small flagellates have 2–4 free apical ► [flagella](#) and a shorter recurrent one that is attached to the surface; ► [mitochondria](#) and ► [Golgi apparatus](#) are missing; their ► [cytoskeleton](#) is similar to that of the trichomonadids. They inhabit the intestine of many invertebrates and vertebrates, feeding by means of their ► [cytostome](#) on the intestinal fluid; their pathogenicity, if any, is always low. In humans, ► [Chilomastix mesnili](#) and ► [Retortamonas intestinalis](#) are found, which reach in general about 5–10 µm in length, reproduce by longitudinal ► [binary fission](#), and are transmitted by oral uptake of fecally passed cysts.

Retortamonas intestinalis

Double-flagellated trophozoites (4–9 µm long, one flagellum occurs at the anterior pole, the

***Retortamonas intestinalis*, Fig. 1** DR of a trophozoite and cyst (F flagellum, N nucleus)

other is a lateral recurrent flagellum originating in a cytostomal channel, Fig. 1), live inside the caecum and colon of humans. They form pear shaped cysts and are claimed to be apathogenic commensals.

Rhabdias bufonis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *rhabdos* = stick (describes the shape of the esophagus).

Classification

Species of Nematodes.

Life Cycle

See Fig. 1.

***Rhabdias bufonis*, Fig. 1** Life cycle of *Rhabdias bufonis*.

1 This worm lives as a protandric hermaphrodite in the lung of frogs and feeds on blood. 2 Eggs are freed via lung air spaces, during which the rhabditiform larvae (L_1) hatch, are swallowed, and are passed with the feces. The filariform L_3 are developed on the soil; some of them may penetrate the skin of the frog (compare 5). 3 Other L_3 grows up to be free-living males and females (about 4 mm long). 4 After copulation, numerous larvae are formed inside the uterus; they

stay inside their mother, mature to the filariform L_3 stage within 5–6 days, feed on the mother's tissues, and are set free after the death of the female. 5 These free L_3 may penetrate the skin of the frog and mature if they reach the lung. 6 When L_3 larvae enter snails, they become accumulated; snails are thus paratenic hosts which must be swallowed in order to transmit the infectious L_3 . AG anal glands, AN anus, E esophagus, GA genital anlage, IN intestine, L larval stages, OV ovary, VU vulva

Rhabditidae

Name

Greek: *rhabdos* = rod.

General Information

Family of free-living ► **nematodes**, which contains (among others) the genera *Rhabdias* (► *Rhabdias bufonis* syn. *Rhabdonema nigrovenosum*), *Rhabditis* = (*Rhabditis strongyloides*, *R. pellio*), and *Pelodera* (*P. strongyloides*).

Rhabdochona denudata

Spiruroid nematode of 6 mm in length, that lives in the intestine of carps. Intermediate hosts are *Cyclops* spp. and larvae of ephemeropteran flies.

Rhabdom

This term describes the central region of an ommatidium of a compound eye. In case that the microvilli of the light perceptive cells fuse, a common rodlike central rhabdom is formed (occurs in most insects) or not (unfused = open rhabdom of ► **Diptera**). ► **Rhabdomer**.

Rhabdomer

The rhodopsin containing microvilli of the light sense cells of arthropods form a paracrystalline structure directed to the center of each ommatidium of the compound eye. This zone of microvilli of such a cell is called rhabdomer, which is underlined by a layer of cisternae containing reserve Ca^{2+} .

Rhabdoviridae

Classification

Family of RNA viruses containing viruses transmitted by arthropods (► [Arboviruses](#)).

General Information

Negative-sense single-stranded RNA viruses (helical, with envelope). Rabies or lyssa are lethal Table 1.

diseases due to the infection with Rhabdoviridae (which are shaped like bullets). Their RNA is enclosed in a nucleocapsid, while the envelope is covered with spines. These viruses may be transmitted by direct bites of infected foxes, dogs, cats, deers of even by bats (► [Vampire Bats](#)).

Important Species

Rhabdoviridae, Table 1 Arboviruses VIII. Negative sense, single-stranded nonsegmented RNA viruses: Family Rhabdoviridae

Serogroup (no. of known members)	Species (selected)	Arthropod host	(Main) vertebrate hosts	Distribution	Disease in man	Disease in animals
Vesiculovirus (9)	Algoas	Phlebotominae Culicidae	Vertebrates	North America Central America South America	Fever	Stomatitis Lameness Loss of milk
	Vesicular stomatitis New Jersey	Muscidae (<i>Musca</i>), Culicidae (<i>Culex</i> , <i>Mansonia</i> , <i>Culiseta</i>)	Cattle, horses, swines	North America Central America South America	Fever	Vesicular stomatitis (stomatitis, lameness loss of milk)

Rhabditiform Larva

► **Hookworms**, second larvae, the esophagus of which is provided with a muscular bulbus (Fig. 1).

Rhinocystidae

Family of mites in the respiratory tractus of birds.

Rhinoestrosis

Disease due to infestation with *Rhinoestrus*, see Table 1.

Rhabditiform Larva, Fig. 1 LM of the rhabditiform larva (*left*), egg (*inset*) of hookworms, sheathed larva (*middle*), and filariform larva (*right*) of *Strongyloides stercoralis*

Rhinoestrosis, Table 1 *Rhinoestrus* species

Parasite	Host	Symptoms	Country	Therapy		
				Products	Application	Compounds
<i>Rhinoestrus</i> spp.	Horse	Swelling of nasal and pharyngeal cavity, cough, loss of strength, death	Worldwide	Eqvalan (Merial)	Oral paste	Ivermectin

***Rhinoestrus purpureus*, Fig. 1** Terminal spiracles of the larva 3 (used for diagnostic purposes)

Rhinoestrus purpureus

Name

Greek: *rhis*, *rhinos* = nose, *oistros* = biting fly;
Latin: *purpureus* = reddish-blue.

The larvae 1 are placed by the flying adult female at the nostrils of horses. They feed portions of the skin and after 2 molts the larvae 3 (Fig. 1) are excreted with nasal and/or pharyngeal slime. On the soil pupation needs 2–5 weeks to let hatch the adults. If larvae 1 are placed onto the eyes, their feeding introduces eventually an extreme conjunctivitis in humans and animals. Respiratory System Diseases, Horses, Swine, Carnivores.

Rhipicentor

Genus of ixodid ticks, the males of which are of medium size, have no ventral plates, but the coxae

of the fourth legs are much enlarged. The basis capituli of adults is very strong with pointed lateral angles. Festoons are present at the posterior end.

***Rhipicephalus* Species**

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The genus *Rhipicephalus* belongs to the group of ixodid ticks and comprises about 80 species, which occur in most cases in Africa. In Europe (especially in southern regions), ticks of the *Rhipicephalus sensu lato* group are common including species like *R. sanguineus sensu stricto*, *R. pusillus* or *R. turanicus*, and some minor important ones. Recent molecular biological comparisons showed that it might be necessary to include several species of the genus ► *Boophilus* into the genus *Rhipicephalus* (see Table 1). Characteristics for the species of the genus are the following criteria:

- Specimens possess eyes (Fig. 1).
- Hypostome and pedipalps are short.
- The basis capituli is sexangular.
- Coxa 1 is divided beyond the midregion.
- Anal groove is situated behind the anus.

Rhipicephalus Species, Table 1 Some important *Rhipicephalus* species and their function as vectors

Species	Stages in life cycle	Hosts of larvae and nymphs	Hosts of adults	Vectorship of agents of diseases
<i>Rhipicephalus appendiculatus</i> ♀ 3–5 mm; fed 1–2 cm ♂ 2.8–3.1 mm Brown ear tick	3	Hares, small mammals, carnivores	Wild and domestic ruminants	<i>Theileria</i> species <i>Anaplasma bovis</i> <i>Rickettsia conorii</i> <i>Babesia bigemina</i>
<i>Rhipicephalus bursa</i> ♀ 2.5–5 mm, fed up to 2.5 cm ♂ 2.5–3 mm Brown ruminant tick	2	House and wild ruminants	Ruminants, rarely horses, dogs and humans	<i>Babesia ovis</i> <i>B. motasi</i> <i>B. major</i> <i>Theileria ovis</i> <i>T. equi</i> <i>Anaplasma marginale</i>
<i>Rhipicephalus evertsi</i> ♀ 2.8–4.4 mm; fed 1.3 cm ♂ 3 mm Two-host tick	2	Small mammals	Wild and domestic ruminants	<i>Theileria</i> species <i>Babesia bigemina</i> <i>Rickettsia conorii</i> <i>Borrelia theileri</i>
<i>Rhipicephalus (Boophilus) microplus</i> Cattle tick	1	Cattle, rarely sheep, wild ruminants, horses	Cattle, rarely sheep, wild ruminants	<i>Anaplasma marginale</i> <i>Babesia bovis</i>
<i>Rhipicephalus praetextatus</i> ♀ 3–4.5 mm; fed 1.2 cm ♂ 3 mm Cattle leg tick	3	Small mammals (mostly murid rodents)	Wild and domestic ruminants and wild carnivores, zebras, camels, warthogs	<i>Rickettsia conorii</i> (also to humans)
<i>Rhipicephalus pulchellus</i> ♀ 3–4.5 mm; fed 1 cm ♂ 3 mm Zebra tick	3	Small mammals	Zebra, eland, ruminants	<i>Theileria parva</i> <i>T. equi</i> <i>T. taurotragi</i>
<i>Rhipicephalus sanguineus</i> ♀ 3–3.8 mm; fed 1 cm ♂ 3–3.5 mm Brown dog tick	3	Mainly dogs, rarely cats, humans	Mainly dogs, rarely cats	<i>Anaplasma platys</i> <i>Rickettsia conorii</i> <i>Ehrlichia canis</i> <i>Hepatozoon canis</i> <i>Babesia gibsoni</i> <i>Babesia vogeli</i> <i>Dipetalonema dracunculoides</i> <i>Cercopithifilaria grassii</i>
<i>Rhipicephalus turanicus</i> Size like <i>R. sanguineus</i> Brown sheep tick	3	Rodents, hedgehog, horses, birds	Sheep, goats, horses, rarely cattle, pigs, dogs, humans	<i>Anaplasma ovis</i> <i>Rickettsia conorii</i> <i>Babesia traubmanni</i> <i>Theileria equi</i>

For further species of this group, see ► [Boophilus](#)

- The general color is brown in both sexes; however, males with their large scutellum appear darker brown.

Although the life cycles of many species of the genus *Rhipicephalus* are not yet fully clarified, some important ones are intensively studied:

Rhipicephalus appendiculatus

Name: Greek: *rhipis* = fan; *kephale* = head.
Latin: *appendiculatus* = provided with an appendix.

Both sexes of this species have sparse interstitial punctatum. The separation of the areas porosae (see Fig. 1) and the pedipalps is slight. The scutum

Rhipicephalus Species, Fig. 1 Diagrammatic representation of the anterior region and of the scutum of the females of different genera of ticks. *A* area porosae, *CH* cheliceres, *E* eyes, *P* pedipalps

is dark, the eyes are slightly convex, and the genital aperture has posterior lips forming a broad V shape. This species is found from South Sudan throughout the southeastern coast of Southern Africa. It is not defined how far west it extends, but it has proven to occur (at least focally) in Zambia and in the Congo region in biotopes such as savannas with temperate climatic conditions but also in hot coastal regions up to humid highland plateaus. Immature stages attach mainly on the neck, cheeks, eyelids, muzzle, and ears, while adults prefer to feed at the pinna of the ear, eyelids, horns, tail, and around the anus. Under favorite conditions, the whole life cycle can be finished within 3 months. This species is a very important vector of agents of diseases (Table 1), so that tick control is highly requested in farms, since cessation of anti-tick treatment can lead to high cattle mortality.

Rhipicephalus bursa

Name: Greek: *rhapis* = fan; *kephale* = head. Latin: *bursa* = sack (describing fully engorged females).

This tick (by Canestrini and Fanzago already described in 1877) occurs predominantly in regions with a mild marine climate (e.g., around the Mediterranean Sea etc.) but also in the Near East, Iran, and Kazakhstan. Sheep are most common parasitized. The parasites are mostly found there in the perianal region, in the ears, and in the inguinal regions. The life cycle for one generation takes mostly only 6–7 months involving two hosts.

Rhipicephalus* (syn. *Boophilus*) *microplus

Name: Greek: *rhapis* = fan; *kephale* = head; *philein* = loving. Latin: *microplus* = small-like.

This species and four others (e.g., *R. decoloratus*, *R. annulatus*; Fig. 1) are one-host ticks, since all stages stay on the same host (mainly cattle). The development from larva until the fully fed female takes mostly only 3 weeks followed by the egg laying on soil, which takes 2–3 weeks. Thus under good climate conditions, 5–6 generations may follow each other leading to enormous amounts of ticks. It is estimated that about 800 million cattle are endangered to become infested.

Rhipicephalus praetextatus

Name: Greek: *rhipis* = fan; *kephale* = head. Latin: *prae* = before, in front; *sextum* = tissue.

This species occurs in Africa in a wide range of climatic regions. It is widespread in most of the

Eastern countries. The immature stages prefer murid rodents, while adults mainly attach in ruminants at the legs (mostly just at the lower regions of the feet) and in the tail brush. They may induce toxicosis in cattle resulting in paralysis, but apparently are of low importance in transmission of cattle diseases. However, it is proven that this species may transmit the viruses of the Nairobi sheep disease and *Rickettsia conorii* to humans causing the so-called tick typhus.

Rhipicephalus pulchellus

Name: Greek: *rhipis* = fan; *kephale* = head. Latin: *pulchellus* = beautiful.

This species, which has flattened eyes and possesses as females an ivory appearing whitish scutum, prefers in contrast to *R. appendiculatus* dry

***Rhipicephalus* Species,**

graph (colored) of a female of *R. sanguineus*

***Rhipicephalus* Species, Fig. 5** Scanning electron micro-
graph of the anterior pole of a female of *R. sanguineus*

R

Rhipicephalus sanguineus

Name: Greek: *rhapis* = fan; *kephale* = head.
Latin: *sanguineus* = bloody red.

This species is a three-host tick (Figs. 1, 2, 3, 4, and 5), which mainly infests dogs, only rarely (10 %) other hosts like cats and even more rarely humans. Originally this species occurred only in the region of the Mediterranean Sea; however, by help of dog importation, it is now found worldwide in regions between 35° south and 50° north. Spreading is still ongoing. It is most important as vector especially of the agents of the canine babesiosis (Table 1). Under good climate condition, a

regions and thus is found in savannas and even in desert-like climatic conditions. It is the most common tick in Northeast Africa and is also found in the Rift Valley and east from there ranging from Eritrea until Tanzania in the south. Preferred hosts are zebras and elands, but they attack also domestic cattle, camels, sheep, and goats. They suck along the ears and underside the body (chest, belly, genital regions) and around the anus. Immature stages, which are common on hares, will readily attach to humans, too.

Rhipicephalus Species,

Fig. 6 Diagrammatic representation of the life cycle stages of *Rhipicephalus sanguineus*. 1 egg; 2 larva; 3 nymph; A–C hosts (blood donors; many species may become infested: cats, sheep, cattle, pigs, hare, rabbits, etc.)

generation takes only 3 months up to 1 year. The observation is important that the larvae may also spread in human domiciles and attack humans. With respect to the fact that females lay 2,000–5,000 eggs, larval infestation of houses may bring enormous problems (Fig. 6).

Rhipicephalus turanicus

Name: Greek: *rhipis* = fan; *kephale* = head. Latin: *furanicus* = belonging to the Persian Turan region (today Turkestan).

This species was often misdiagnosed as *R. sanguineus* or *R. sulcatus*, since there exist several strains, which had been described in the Palaearctic or in the Afrotropical regions.

T. turanicus is a three-host species (see Table 1) showing the absolutely broadest host range in the whole genus. Characteristic is that the ears of hosts are the most preferred sites of attachment. Especially sheep are the most common hosts, since they live in subhumid and semiarid habitats, which cover coastal regions of the Mediterranean Sea, and thus *R. turanicus* is found in Spain, South France, Italy, and in the Tessin in Switzerland.

Further Species of Rhipicephalus

- ***R. bergeoni*:** This species parasitizes on Artiodactyla (Bovidae) and is apparently restricted to Sudan and Ethiopia.

- ***R. camicasi***: This species is found as well on Bovidae as on Camelidae in Northern Africa (Egypt) but also found in Sudan, Ethiopia, Somali, and Kenya.
- ***R. leporis***: This species is a parasite of many species of Leporidae and Canidae and occurs in Central Asia East of the Caspian Sea.
- ***R. pumilio***: This species parasitizes at several mammals and birds and was also found on **humans**. Regions of occurrence are Asian countries.
- ***R. pusillus***: Found on European rabbits (*Oryctolagus cuniculus*) and occurs in the countries of the Western Mediterranean Sea.
- ***R. schulzei***: This species is found mainly on Rodentia and Lagomorpha and occasionally on humans in Central Asia.
- ***R. sulcatus***: This species is mainly found on mammals in Central and Western Africa.

According to listing by Gray et al. (2013).

Protection Treatment

Protection of Humans

Use of repellents, which have to be sprayed on the shoes, on socks, on trousers, and on naked space of legs. Effective products are high doses of ► **DEET**, Saltidin (icaridin), or a combined product of Saltidin plus Monk pepper extract (Viticks® of Fa. Alpha Biocare, Germany: www.alphabiocare.de).

Protection of Animals

Most effective are modern contact acarizides such as diazinon, amitraz, carbamates, and propoxur/flumethrin (depending on the legal regulation situation in each country, since in case of animals, protective products are legally considered as medicaments).

Rhizopoda

From Greek: *rhiza* = root, *pus/podos* = foot.
► **Amoebae**.

Rhoptries

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

From Greek: *rhopalon* = club. This term describes clubbed cell organelles (mostly two) at

the apical pole of motile stages (► [merozoites](#), sporozoites) of ► [Apicomplexa](#), which are active during the process of penetration into their host cell. These bulbous organelles (first called paired organelles) start immediately at the inner side of the cell membrane and stretch into the interior of the first third of sporozoites, merozoites, endozoites, cystozoites, etc. Their apical pole (neck) has a small diameter, while their terminal portion (bulb) is swollen (e.g., in *Eimeria* species or *Toxoplasma gondii*) and in some species nearly spherical in diameter (e.g., in *Plasmodium* species (Figs. 1 and 2). In species with an apical ► [conoid](#) (e.g., *Eimeria*, *Toxoplasma*, *Sarcocystis*, etc.), the apical portions of the rhoptries pass the protrudable conoid (Fig. 1), while in the case of the conoid-less *Plasmodium* species the neck of the rhoptries is found inside the opening of the apical ► [polar ring](#), which is formed by thickenings of the two inner layers of the ► [pellicle](#) of the motile stages (sporozoites, merozoites). To date, more than 30 proteins have been classified as typical rhoptry proteins (e.g., in *P. falciparum*). However, many more are not yet determined. The proteins in the neck region differ considerably from those packed in the terminal bulb. Several neck proteins (RONs) are found to be conserved between motile specimens of the genera *Toxoplasma*, *Eimeria*, and *Plasmodium*, while bulb proteins (ROPs) are in general species

specific. However, it is clear that all have their function during host cell penetration, since afterward the rhoptries mostly disappear.

The process of cell penetration starts by adhesion (mediated by adhesins) of the parasite at the host cell membrane. This is followed finally by the formation of a dynamic tight junction between the apical pole of the invading motile parasitic stage (e.g., merozoite, tachyzoite, etc.) and the host cell. This peculiar tight junction is referred to as moving junction.

In the case of *Plasmodium* merozoites (Fig. 2c, MJ), this moving junction is predicted to consist of a complex of rhoptry neck proteins (RON2, RON4, RON5) plus the microneme protein AMA1.

In contrast to the neck proteins of the rhoptries, the bulb proteins function apparently predominantly downstream of invasion. For example, in *Toxoplasma gondii*, these ROPs (being completely different from those of *Plasmodium* species) are kinases that interact with host signaling pathways and interfere with host immunity. Both functions enhance the survival chances of the invaded parasitic stage inside its host cell. However, in *Plasmodium* species, these ROPs have apparently no kinase activity but seem to be involved in strengthening the formation of the parasitophorous vacuole. Other ROPs are involved in evasion of host cell attacks.

Rhoptries,

Fig. 1 Transmission electron micrograph of a longitudinal section through the anterior pole of a tachyzoite of *Toxoplasma gondii*; note that the ductules of the rhoptries pass through the conoid, while their posterior club-shaped portions have a spongy interior (brownish colored)

Rhoptries,

Fig. 2 Diagrammatic representation of merozoites of *Plasmodium* penetrating the erythrocyte. Note that the rhoptries (*RH*) are at first club-shaped and after penetration rather spherical. DB = dense body; DV = apicoplast; E = erythrocyte; EP = developing PV; MI = mitochondrion; MJ = moving junction; MN = micronemes; N = nucleus; PV = parasitophorous vacuole; RH = rhoptries; SC = surface coat; Z = cell membrane of erythrocyte

Rhynchobdellida

From Greek: *rhynchos* = mouth, *bdellein* = sucking. ► [Leeches](#).

Rhynchophthirina

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

These lice are more closely related to ► [Mallophaga](#) (biting lice) than to ► [Anoplura](#) (blood sucking lice). They are called elephant

lice due to the fact that their head has an elephant-like snout and occurs on elephants. The adult stages are small measuring only 3 mm in length.

After fertilization, the females excrete via the sexual opening daily 1–12 eggs (about 200 during lifetime). The sexual opening is exclusively used for egg deposition – never for entrance of sperms.

Rhynchota

Name

Greek: *rhynchos* = sucker.

Synonyms

Bugs, Hemiptera.

Classification

Order of insects that includes the bloodsucking bugs, but also plant feeders.

Ribaga'ibagaot

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Pocket-like organ, which is subcutaneously situated at the ventral side (between 4th and 5th abdominal segment) of female bed bugs (► *Cimex lectularius*). This organ is filled during copulation with sperms that are injected by help of the hook-like ► *aedeagus*, which penetrates ventral body cover of the females. The sperms finally reach via the hemolymph the receptaculum seminis, which is situated close to the ovaries.

Ribeiroa

Genus of ► *trematodes*. Infections with *R. ondatrae* lead to malformations in amphibian development. Thus, this parasite acts teratogenically, e.g., up to 50 % of the leopard frogs (*Rana pipiens*) in North America show such a disease.

Ribeiroia ondatrae

Species of digenetic trematodes, which reach a length of 1.6–3 mm and parasitize in the proventriculus of chickens, fish-eating birds and muskrats. Their testes are situated at the posterior end, the ovary lays before the testes. The eggs measure about $85 \times 45 \mu\text{m}$. The disease is named proventriculitis. Infections with *R. ondatrae* lead to malformations in amphibian development. Thus this parasite acts teratogenically, e.g., up to 50 % of the leopard frogs (*Rana pipiens*) in North America show such a disease.

Riberoria

Genus of digenetic ► *trematodes*, the ► *cercariae* of which enter tadpoles and introduce deformities. The adult frogs are later disabled in their movement and thus are easy prey for birds, which are the final hosts of these ► *flukes*. Since some Insecticides may lead to similar deformities, they were suspected as agents of these diseases.

Riboflavin Deficiency

The vitamin B₂-deficiency occurs during ► [malaria](#). Thus the application of this vitamin offers a kind of protection against the severeness of symptoms.

Ribosomes

The ribosomes consist of RNA and protein (► [Nuclear Division](#), Fig. 5, ► [ReserveGranules](#), Fig. 1A). The ribosomal RNA represents about four-fifths of the total cellular RNA. There are several types of ribosomes, depending on the nature of their subunits (► [Eukaryota](#), Table 1); these subunits can be released by appropriate treatment of the ribosomal proteins. Several ribosomes often align in a chain to form polyribosomes, or polysomes, where they are collectively active in protein synthesis. Ribosomes occur along the surface of the rER, either as single forms or as polysomes. They also occur in the ► [cytoplasm](#) and inside the ► [mitochondria](#). In ► [Protozoa](#), cytoplasmic ribosomes have a diameter of ca. 30 nm and are composed of 2 subunits with sedimentation characteristics of 60S and 40S. The intact ribosome is of the 80S type. Mitochondrial ribosomes are of the 70S type or, in ciliates, 80S. The mitochondrial ribosomes are similar to those of ► [prokaryotes](#) (► [Eukaryota](#), Table 1).

Richness, Parasitic

Parasitic richness can be defined as the number of parasite species that are found in a given host species. The question may be answered at different scales: total richness (the number of parasite species in the whole area of the host),

regional richness (the number of parasite species in a “region,” for instance, a river basin, an island, etc.), the local richness (the number of parasite species in a particular population of the host).

Parasitic richness is very variable; as an example, Caro et al. showed that certain species of Mediterranean fish harbour more than 10 species of monogeneans (the case of certain Sparidae), whereas others harbour none (the case of all Gobiidae, Syngnathidae, and Blenniidae). Hochberg and Hawkins note that one insect species can be attacked by a number of parasitoid insect species ranging from a few to 50 or more. Examples could be multiplied to show that parasitic richness is not a random process: in the same group of hosts, certain species are “rich” in parasites, others are “poor.”

The explanation of the diversity of parasitic richnesses has been looked for in various directions. The method of “comparative analysis” consists in gathering data for numerous host species and trying to determine whether the same factors (e.g., an aquatic environment, a particular type of diet, a large size) produce the same effect on the parasitic richness of the different host species.

Comparative analyses are confronted with 2 difficulties:

One consists in the great differences which usually exist in sampling effort for the different host species.

Another is that the variables used in the analysis are rarely independent. In particular, a part of the parasite richness can be the result of ► [coevolution](#) and therefore does not necessarily reflect the present-day conditions. For instance, if 2 host species have a common ancestor, their parasitic richness can be inherited in part from this ancestor and its dependence on current environmental factors is limited.

To overcome these 2 difficulties, comparative analyses are corrected both for sampling effects and for phylogenetic effects by mathematical procedures. The validity of comparative

analyses and especially of the correction for phylogenetic effects has been the subject of discussions.

There is a general agreement that the following factors influence positively the parasitic richness of host species:

- the host's body size;
- the diversity of micro-habitats offered by the host organism;
- the geographical area of the host species;
- a diversified diet which implies the ingestion of a variety of potential intermediate hosts;
- gregarious behaviour on the part of the host species.

Other factors influence negatively the richness of parasite communities; they are principally factors opposite to the ones just listed but they also include the existence of “refuges” which act as shields against infective stages.

Parasitic richness can be also measured in individuals within a population of hosts. At this scale again, the distribution of individual parasites is seldom random but is nearly always “contagious” (the variance is significantly greater than the mean): certain host individuals harbour more parasites (sometimes much more) than predicted by a random distribution. Parasitic richness at the scale of individuals is called “parasitic intensity” by most authors. Individual differences in parasitic intensity are explained by differences either in exposures to infective stages (different behaviour of different individual hosts), or in success of parasitic development after infestation (different efficacy of immune systems).

Ricketts, Howard Taylor (1871–1910)

American microbiologist (Fig. 1, page 1251), discoverer of the agents of disease of the Rocky Mountain spotted fever (*Rickettsia rickettsi*) and its transmission by the bite of the tick *Dermacentor occidentalis*. He died in 1910 from this disease during an expedition in Mexico; he was only 39 years old.

Ricketts, Howard Taylor (1871–1910), Fig. 1 Ricketts prior to leave to his last Mexico expedition

Rickettsia prowazekii

Agent of the spotted fever disease transmitted by faeces of body lice, named in honour of two scientists ► [Ricketts](#) and ► [Prowazek](#), who both died while working with rickettsiales.

Rickettsia Species: Selected Species, Vectors, Diseases, Geographic Distribution

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Rickettsia species are named honouring the American scientist Howard Taylor Ricketts (1871–1910) The genus comprises rod-shaped

***Rickettsia* Species: Selected Species, Vectors, Diseases, Geographic Distribution, Table 1**

Species	Vectors	Diseases	Region
<i>R. aeschlimanni</i>	<i>Hyalomma</i> sp., ticks	Tick bite fever	Africa
<i>R. africae</i>	<i>Amblyomma</i> spp, ticks	Tick bite fever	Africa, South Africa
<i>R. akari</i>	<i>Liponyssoides</i> spp., mites	Rickettsial small pocks	USA, Europe, Balcony, Africa
<i>R. australis</i>	<i>Ixodes</i> spp., ticks	Queensland tick bite fever, spotted fever	Australia, Tasmania
<i>R. conorii</i> + subspecies	<i>Rhipicephalus</i> sp. ticks	Mediterranean spotted fever	Mediterranean regions, Near East, Africa
<i>R. felis</i>	<i>Ctenocephalides</i> sp., fleas	Flea-tick bite fever	Africa, Asia, Central Europe, Americas
<i>R. heilongjiangensis</i>	<i>Dermacentor</i> , <i>Haemaphysalis</i> species, ticks	Far East tick bite fever	China, Japan, East Russia
<i>R. helvetica</i>	<i>Ixodes</i> spp.	Aneruptive tick bite fever	Eurasia
<i>R. honei</i>	<i>Aponomma</i> , <i>Rhipicephalus</i> species, ticks	Flinder's Island, Thailand tick bite fever	Australia, Thailand
<i>R. japonica</i>	Many ticks	Eastern tick fever	Japan
<i>R. marmioni</i>	<i>Hyalomma</i> , <i>Ixodes</i> spp., ticks	Australian tick bite fever	Australia
<i>R. massiliae</i>	<i>Rhipicephalus</i> spp., ticks	Tick bite fever	Europe
<i>R. parkeri</i>	<i>Amblyomma</i> spp., ticks	Maculae fever	North, South America
<i>R. prowazekii</i>	<i>Pediculus humanus corporis</i> , lice	Louse spotted fever	Asia, Americas, Africa
<i>R. rickettsii</i>	<i>Amblyomma</i> , <i>Dermacentor</i> , <i>Rhipicephalus</i> spp., ticks	Rocky Mountains spotted fever	Americas
<i>R. sibirica</i>	<i>Haemaphysalis</i> , <i>Dermacentor</i> , ticks	Nord Asia tick bite fever	Russia, China, Mongolia
<i>R. typhi</i> (syn. <i>R. mooseri</i>)	<i>Xenopsylla cheopis</i> , <i>Ctenocephalides</i> sp., fleas	Murine spotted fever	Americas, Asia, Africa, Europe

bacteria, which develop inside host cells and are vector-transmitted (Table 1).

RNA Editing

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

RNA editing is one of the most striking phenomena observed in the mitochondria of kinetoplastids including *Trypanosoma* and *Leishmania*. In this process, mitochondrial (mt) pre-mRNA, encoded by the ► [kinetoplast DNA](#) (kDNA) maxicircles, is posttranscriptionally modified by insertion and deletion of uridine nucleotide (U) residues under the direction of small RNAs, termed ► [guide RNAs](#) (gRNAs). It is a form of RNA processing that finally results in the formation of mature translatable mRNA, but it is distinct from the widely occurring RNA splicing and other types of RNA processing, since additional sequences in the form of U residues are created after transcription. Trypanosome RNA editing is catalyzed by multiprotein complexes (editosomes) and occurs at multiple sites, contributing over half of the protein-coding residues of certain mRNAs. The number of minicircles present in kDNA is

sufficient to encode all the gRNAs required for editing of the mitochondrial transcripts. *Trypanosoma brucei* contains roughly 50 identical 22-kb maxicircles and more than 200 1-kb minicircle classes that can encode more than 1,000 gRNAs. The biological relevance of RNA editing is not understood but it probably functions, for example, to regulate expression of the mitochondrial respiratory chain during the life cycle of trypanosomatids. It appears to provide a selective advantage to these organisms and thus its early origin in evolution was retained.

RNA Editing Core Complex

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This complex, which is also named as L-complex (Simpson et al. 2004) or as 20S editosome (Stuart et al. 2005), contains about 20 proteins which encapsulate the enzymatic activities that are needed for a single round of uridine insertion respectively deletion editing. See Kinetoplastid RNA.

Rochalimea

Lice-transmitted bacteria now belonging to the genus *Bartonella* (► [Trench Fever](#)).

Rochalimea quintana

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Old name for ► *Bartonella quintana*, the agent of the so-called 5-day fever or Trench fever. See ► [lice](#).

Rocky Mountain Spotted Fever

Rocky Mountain spotted fever is caused by *Rickettsia rickettsi*. It is found from Canada to South America and is associated with various ixodid

► [ticks](#) (*Dermacentor andersoni* and *D. variabilis* in North America) which can transmit the pathogen transovarially to the next generation. All tick stages can harbor and transmit agents of the disease. Argasid tick species may also be involved. The disease can be acquired through the tick bite or through contact with tick tissues when the tick is crushed. The ► [incubation period](#) is 2–5 days in severe cases and up to 14 days in mild cases. In untreated cases, death occurs 9–15 days after onset of symptoms. Mortality was formerly high but has been reduced through antibiotic treatments (tetracyclines).

SAFC Concentration

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This is a method to isolate parasitic stages from feces respectively stools of animals or humans by help of a so-called sodium acetate-acetic acid-formalin solution.

SAFC

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term is an abbreviation for Sodium acetate-acetic formalin concentration method being used

1. Stool sample (1 g) is placed into a tube containing 10 ml of S.A.F.
2. Stool and S.A.F. are intensively mixed by a glass stick.
3. Closed tube is shaken vigorously.
4. Stool is filtered using a funnel with gauze.
5. The tubes are now centrifuged for 1 minute at 2,000 rpm.

6. Supernatant is removed by help of a pipette or cautiously decanted.
7. 7 ml saline is added and contents are mixed with a glass stick.
8. 3 ml ether has to be added.
9. Tubes are closed with rubber stoppers, well shaken, while fixing firmly the stopper (or closing the vessel by a cover).
10. The cover (or rubber stopper) is removed and the product is centrifuged for 5 min at 2,000 rpm.
11. After centrifugation all three upper layers were decanted and just the sediment is retained and investigated by help of a light microscope (use a cover slip placed onto the removed droplet of the sediment).

This procedure was recommended by Swiss Tropical Institute, Bale, Switzerland.

Saltidin/Icaridin

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Structural Formula

Saltidin

Structural formula

General

Trade name	Saltidin
Other Names	KBR 3023, Bayrepel, Propidin, Picaridin, Icaridin
Elemental formula	C ₁₂ H ₂₃ NO ₃
Chemical name	2-(2-Hydroxyethyl)-piperidin-1-carbonic acid-1-methylpropylester
CAS number	119515-38-7
EU number	423-210-8
Appearance	Clear oily fluid

Properties

Molecular mass	229.3 g/mol
Density (20 °C)	1,037 g/cm ³
Freezing point	< -170 °C
Boiling point	273 °C at 1,013 hPa
Ignition temperature	375 °C
Flash point	142 °C
Vapor point	0 hPa at 20–50 °C
Water solubility (20 °C)	8.6 g/l
Acetone solubility (20 °C)	>250 g/l
Stability in water	Stable at pH 5–9 and 20–25 °C

(continued)

Saltidin	
Safety instructions	
Toxicity	1. LD₅₀ oral rat 2,236 mg/kg KGW 2. LD₅₀ dermal rat approximately 5,000 mg/kg/ KGW 3. LD₅₀ inhalation: rat approximately 4,364 mg/m³ 4. Skin irritation: rabbit, none at 4 h exposure 5. Eye irritation: rabbit, slight at 24 h exposure 6. Sensitivity: none in guinea pigs 7. Phototoxicity: none
Skin penetration humans (0.63 mg/cm ²)	Very low, ~3.8 %; only 1.7 % of the dose is found in urine
Genotoxicity	Negative: Ames test at <i>Salmonella typhimurium</i>
Mutagenicity	Negative: rat liver cell culture
Carcinogenicity	Negative: mice at 18 months of exposure
Reproduction toxicity	Negative: rats at 20 days of skin application
Neurotoxicity	Negative: rats at 13 weeks of exposure
Ecotoxicity (examples)	Acute toxicity for fish (<i>Oncorhynchus</i> spp.) after 96 h of exposure: LC ₅₀ at 173 mg/l LC ₁₀₀ at 240 mg/l
	Toxicity for birds (<i>Colinus</i> spp.) LC ₅₀ > 5,000 ppm at 5 days of exposure
Bioaccumulation	None (fish test)

Definition

Repellents (*Latin*: repellere = to repulse) are compounds that protect humans and animals from an approach and blood feeding by arthropods.

History

For thousands of years, blood-feeding arthropods have been attacking humans and their animals,

leading to nasty itchy wounds and considerable discomfort. The bites can often be very painful. Mankind has suspected for many hundreds of centuries that the agents of diseases might be transmitted during such bites. This was finally proven, when famous English scientists such as Ross and Manson detected, for example, the mosquito-based transmission of malaria (1897) or the transmission of filarial worms, or when the French physician Simond discovered in 1898 the transmission of plague bacteria by fleas, as was shown by Grüntzig and Mehlhorn (2010).

Therefore, attempts to fend off blood-suckers and to avoid their bites are probably as old as recent humans (*Homo sapiens*). The wealthy “Old Greeks” and their skilful Roman successors left their houses in the depths of the valleys, where mosquitoes had favorable breeding sites, and built their houses on the top of mountains. The humans of the early high cultures used the smoke of their open fires to keep away the flying armada of nasty bloodsuckers. They developed and used a large amount of sophisticated plant extracts that were spread not only on the skin of the ladies of high society, but were also used by the common population. Among the broad number of useful compounds, the rose oils, *Citronella* oils and also olive oils were predominant. Of course, the repellent activity was and is still limited to a rather short period of 1–2 h – if at all. Thus, it is understandable that after 1900 (when the chemical sciences began to flourish) the search for highly active compounds against mosquitoes and ticks started, and is still ongoing.

Dimethyl phthalate (DMP) was the first relevant compound to be introduced in 1929 in a wide spectrum of countries. However, its activity period was rather short and only a few arthropod species were kept away from bodies treated with it. Today, this compound is considered to be harmful to the skin, but is still used as means of softening and/or diluting other compounds (Legrum 2011; Lorz et al. 2007). Further research activities in this field led to the launching of new repellents indol and 2-ethyl-1,3-hexandiol (Rutgers 612). As these products also had rather weak repellent effects, research continued – especially in the

laboratories of the Army of the United States of America. In large series of experiments the substance diethyltoluamide (DEET) was detected and first used by American soldiers in Asia during the Korean War (1950–1953). Further intense research activities made it possible for DEET to be offered in 1955 to the civil population in the USA and other countries worldwide, where it is now the most commonly used repellent, although incorrect applications have led to severe damage to health – fatalities have even been reported in the relevant scientific journals (Reuveni and Yagupski 1982; Stinecipher and Shaw 1997; Tenebein 1987).

These potential health problems due to DEET, and the fact that this compound leads to a sticky feeling on the skin combined with a bad smell, that it damages plastics (e.g., bracelets, watches, belts, shoes, etc.) and that it has rather poor activity against ticks, made it necessary for many government institutes and private chemical companies to start intense research projects designed to find more convenient synthetic substances that might replace DEET. Thus, Bayer AG of Leverkusen (Germany) started broad research projects more than 20 years ago.

Research Goals

The research projects of Bayer AG had the goal of developing a synthetic compound to solve the following problems:

- (a) Humans should be protected from the direct effects of insect or tick bites (e.g., severe itching, allergic reactions; Figs. 1 and 2).
- (b) Humans should be protected from the transmission of severe agents of diseases (viruses, bacteria, protozoans, worms) during blood meals (Table 1).
- (c) The product should ensure maximum safety when spread on human skin.
- (d) The new product should feel pleasant on the skin and avoid any stickiness (as is the case when using DEET).
- (e) The compound should not damage shoes, clothes, spectacles, bracelets, watches, etc.
- (f) The compound should not endanger the environment when introduced into lakes (e.g., during bathing).
- (g) Furthermore, a very broad activity was an essential goal, because in the open air and at home, humans may be attacked by a wide spectrum of bloodsuckers (e.g., mosquitoes, biting flies, midges, black flies, sand flies, tabanids, ticks, mites, fleas, bugs) – often at the same time.

Saltidin/Icaridin, Table 1 Important agents of diseases and their vectors

Vectors	Causative organisms	Diseases	Medication/vaccination availability
Mosquitoes <i>Aedes aegypti</i> , <i>Aedes albopictus</i> + other <i>Aedes</i> species	Alpha virus	Chikungunya fever	No vaccination and no medication available
<i>Aedes aegypti</i> , <i>Aedes albopictus</i> + other <i>Aedes</i> species	Flavivirus	Dengue fever	No vaccination and no medication available
<i>Aedes aegypti</i> (urban cycle), <i>Aedes</i> species (rainforest cycle)	Flavivirus	Yellow fever	Vaccination available, no medication
<i>Aedes japonicus</i> , <i>Culex</i> species	Flavivirus	Japanese B encephalitis	Vaccination available, no medication
<i>Culex</i> species, <i>Anopheles</i> species	Flavivirus	West Nile fever	No vaccination
<i>Culex pipiens</i> , other <i>Culex</i> species	Flavivirus	St. Louis encephalitis	No vaccination
<i>Aedes caspius</i> , <i>Aedes vexans</i> , <i>Culex</i> species	Bunya virus	Meningitis, fever	No vaccination
<i>Aedes</i> species, <i>Culex</i> species, <i>Anopheles</i> species	Bunya virus	Rift Valley fever	No vaccination
<i>Anopheles</i> species	<i>Plasmodium</i> species (Protozoa)	Malaria	Full vaccination: not available, chemoprophylaxis available, chemotherapy available
<i>Culex</i> species, <i>Anopheles</i> species, <i>Aedes</i> species	<i>Wuchereria bancrofti</i> , <i>Brugia malayi</i> , Filariae, Nematodes	Filariasis: tropical elephantiasis	Medication available, but not completely effective
<i>Culex</i> species, <i>Anopheles</i> species, <i>Aedes</i> species and <i>Culiseta</i> species	Skin filariae, <i>Dirofilaria</i> species	Skin filariasis	Surgical extraction of skin nodules recommended; some medication available
Black flies <i>Simulium</i> species and related species	Eye and skin filariae, e.g., <i>Onchocerca volvulus</i>	Onchocerciasis, river blindness	Medication stops only fertility of females
Biting flies <i>Glossina</i> species	<i>Trypanosoma brucei</i> subspecies (Protozoa)	Sleeping sickness	Chemotherapy possible, but has severe side effects
Sandflies <i>Phlebotomus</i> species, <i>Lutzomyia</i> species	<i>Leishmania</i> species (Protozoa)	Leishmaniasis	Chemotherapy available
<i>Phlebotomus</i> species, <i>Lutzomyia</i> species	Phlebovirus	Sandfly fever	No vaccination available
Tabanids <i>Chrysops</i> species	<i>Loa loa</i> , Eye filaria = wandering filaria	Loiasis	Chemotherapy poor, surgical extraction of wandering adults (♀, ♂) possible
Midges <i>Culicoides</i> species	Bunya virus	Oropouche and related fevers	No vaccination
Lice <i>Pediculus humanus corporis</i>	<i>Rickettsia prowazekii</i>	Lice spotted fever	Medication available

(continued)

Saltidin/Icaridin, Table 1 (continued)

Vectors	Causative organisms	Diseases	Medication/vaccination availability
Fleas <i>Xenopsylla cheopis</i> and other flea species	Bacteria: <i>Yersinia pestis</i> Rickettsiales: <i>Rickettsia typhi</i> <i>Rickettsia felis</i> Tapeworms: <i>Dipylidium caninum</i>	Plague Spotted fever Cestodiasis	Medication available Medication available Medication available
Raptor bugs <i>Triatoma</i> and other species	<i>Trypanosoma cruzi</i> (Protozoa)	Chagas disease	Chemotherapy available, but difficult, with severe side effects
Ticks <i>Ixodes ricinus</i>	Bacteria: <i>Borrelia burgdorferi</i> and related species	Borreliosis Lyme disease	Medication available
<i>Ixodes ricinus</i> <i>Ixodes persulcatus</i>	Flavivirus Flavivirus	Spring–summer encephalitis, Russian spring–summer encephalitis	Vaccination available Vaccination available
<i>Ornithodoros moubata</i> , <i>O. savignyi</i> (both are soft ticks)	<i>Borrelia duttoni</i>	Tick-borne relapsing fever	Medication available
<i>Dermacentor</i> , <i>Rhipicephalus</i> , <i>Amblyomma</i> , <i>Haemaphysalis</i> and <i>Ixodes</i> species	Bacteria: <i>Coxiella burnetii</i>	Q fever	Medication available
<i>Dermacentor andersoni</i> , <i>D. variabilis</i>	Rickettsiales: <i>Rickettsia rickettsii</i>	Rocky Mountains spotted fever	Medication available
<i>Rhipicephalus sanguineus</i>	Rickettsiales: <i>Rickettsia conorii</i>	Spotted fever of the Mediterranean Sea	Medication available
<i>Amblyomma hebraeum</i>	<i>Rickettsia africae</i>	African tick bite fever	Medication available
<i>Amblyomma</i> , <i>Hyalomma</i> , <i>Dermacentor</i> , <i>Boophilus</i> , <i>Ixodes</i> species	CCHF virus, Bunyaviridae	Crimean–Congo fever	No vaccination available
<i>Dermacentor andersoni</i>	Orbi virus	Colorado tick bite fever	No vaccination possible
Mites <i>Trombicula</i> (<i>Neotrombicula</i>) <i>akamushi</i>	Rickettsiales: <i>Orientia tsutsugamushi</i>	Tsutsugamushi fever	Medication available

The product Saltidin (= Icaridin, old local name), which was finally selected from thousands of tests, fulfilled all these goals and is today a modern and safe repellent.

levels of activity and safety had been proven in detail.

S

Success in Research

After several years, and finally testing more than 800 new, synthetically developed substances, these research activities were crowned by the finding of a promising substance called **KBR 3023**. The European patent was then granted in 1988 ([Europäisches Patent](#)) after the required high

Recent Product Name

Saltidin (synonyms: KBR 3023, Bayrepel, propidin, icaridin, picaridin) is a compound, which is named according to the distributing company **Saltigo**, a subsidiary company of **Lanxess** within the Bayer group. **Saltidin** (see overview table) is now the essential component of many repellent products that are distributed worldwide,

as it is active against ticks, mites and many species of blood-feeding insects.

Host Recognition of Blood-Feeding Arthropods

Insects, ticks and mites that feed on the blood of mammals have acquired species-specific systems to find a suitable host (Dettner and Peters 2010; Grüntzig and Mehlhorn 2010; Jensen and Mehlhorn 2009; Mehlhorn 2008; Mehlhorn and Mehlhorn 2009, 2010). **Mosquitoes** have evolved large compound eyes (Fig. 3), which help them to recognize potential hosts, even from far away. Tiny sensilla, which are found on the surface of the whole body and in increased numbers on the head, on its appendices and on its mouthparts, make it possible to recognize even the finest perspiration of potential hosts as soon as they fly close by. Peculiar sensilla of taste become active, when the bloodsuckers have touched down onto the skin of a host (Dettner and Peters 2010; Mehlhorn 2008). These highly varying and species-specific organs of perception (Fig. 3) are

Saltidin/Icaridin, Fig. 3 Scanning electron micrograph of the head of a female *Anopheles* sp. showing a large variety of sensilla

able to detect very small traces of the different odors excreted by the hosts (Table 2).

The skin of humans and animals excretes cocktails of about 30–40 different compounds at varying concentrations depending on the host species and on the status of activity (sleeping, running, etc.). Of these compounds, some are common and prominent: CO₂, butyric acid, lactic acid, fatty acids, adenosine triphosphate, etc. The combination of these compounds within the perspiration of humans and animals are differently attractive to a given species of blood feeders. For example, some species of mosquitoes prefer odors exclusively of animals (e.g., birds), whereas other mosquitoes are multifeeders, attacking the next possible host, including man. However, variations in the recognition of different skin-derived odors (Dettner and Peters 2010) may be enormous – even in closely related species (Table 2). Thus, different human individuals are also differently attractive to the same mosquito species, if they stay or sleep close together. However, if a mosquito has no choice between differently attractive hosts, it will attack the person who is present. There are widespread myths on “sweet” blood that is able to attract mosquitoes – but all these beliefs are incorrect, because blood is merely a well-balanced salt buffer system and attractivity to mosquitoes is simply based on the

Saltidin/Icaridin, Table 2 Gradients of perception (ED50/mol/l) of adenosine triphosphate (ATP), adenosine diphosphate (ADP) and adenosine monophosphate (AMP) of different bloodsuckers (according to Galun and Kabayo, cited by Dettner und Peters 2010). Having reached ED50 mol/l, about 50 % of the blood feeders start their sucking process

Species	ATP	ADP	AMP
<i>Aedes aegypti</i>	1.2×10^{-5}	1.9×10^{-4}	4.6×10^{-4}
<i>Aedes caspius</i>	9.1×10^{-6}	1.5×10^{-4}	3.1×10^{-4}
<i>Culex pipiens</i>	2.5×10^{-5}	1.2×10^{-4}	2.7×10^{-5}
<i>Simulium venustum</i>	2.1×10^{-1}	6×10^{-6}	1×10^{-4}
<i>Glossina palpalis</i>	5×10^{-7}	6.7×10^{-7}	1×10^{-4}

different balanced skin evaporation of the individual under attack.

Among the hard ticks there are species that possess eyes (e.g., *Dermacentor reticulatus*, *Amblyomma hebraeum*, *Rhipicephalus sanguineus*), which consist of a single lens allowing the movements of potential hosts to be detected at a distance of a maximum of around 10 m without seeing in detail. Thus, they start running towards these hosts after having noticed them and need only a few minutes for this journey. Other species of hard ticks, however, are eyeless (e.g., *Ixodes ricinus*, *Haemaphysalis* species) and depend on their special host detection system called Haller's organ. This system consists of a perception groove at the tarsus of each of the anterior pair of legs (Fig. 4). Within this groove, groups of different sensilla are present, which are able to detect the odors of potential hosts or

ground vibrations or air movements of arriving and passing hosts. If the host is recognized by the "brain" of these ticks, they immediately stretch the pair of forelegs in the direction of the arriving host. These legs are equipped with claws (Fig. 5), which allow attachment to a potential host, if it passes by.

Action of Repellents

The details of the actions of the different repellents available on the international market are not completely understood, because the various species of arthropods attacking humans possess a large variety of systems that allow the perception of the odors of potential hosts. However, there are two different modes of action discussed, which may occur alone or act in synergy. The fact is that

Saltidin/Icaridin,

Fig. 4 Above: scanning electron microscopy of the tarsus region of the front leg of the tick *Ixodes ricinus*. Sensillae are seen protruding from a groove (Haller's organ). Below: diagrammatic representation of the nerves in Haller's organ

Saltidin/Icaridin,

Fig. 5 *Anopheles stephensi* (female of the malaria mosquito while sucking a sugar solution)

each repellent starts to vaporize as soon as it comes into contact with the skin. Thus, a tiny “cloud” of vapor is formed, covering the surface of the treated person. This cloud apparently covers the different substances found on human skin in a person-specific arrangement comprising carbon dioxide (CO₂), salts (NaCl), lactic acid, urea, volatile fatty acids, cholesterol, degenerating bacteria, etc. This layer is kept constant by typical perspiration (consisting of 99 % water and containing up to 40 or more different substances, including those cited above, reaching a pH of around 4.5). This composition of different substances is differently attractive to the various species of bloodsuckers. Because the composition of the surface layers of the human skin varies not only in each person but changes during different activities (running, walking, sleeping, etc.), attractiveness to bloodsuckers also varies. Furthermore, the blood-feeding arthropods have varying periods of activity during daytime and at night. For example, many *Culex* species prefer to bite indoors mainly at around 10 p.m. and at around 4 a.m., whereas several *Aedes* species feed in the afternoon. In addition, the mosquitoes select the most suitable places for their bites. Thus, they are able to find even small spots on the skin where the composition of the skin substances is most attractive to them. Such places may be spots that have been left out during spraying of a repellent, where the repellent was wiped away or where the

repellent was diluted by intense sweating. All this together explains why repellents sometimes appear to hide humans well and sometimes less well, from attack by blood-feeding arthropods.

Another theory to explain the effects of the different repellents is based on the assumption that the cloud of the repellent evaporating from the skin disturbs the efficacy of the smelling sensilla of the attacking insect for a while. However, this effect – if present at all – does not last very long, as it can be observed that mosquitoes that landed on a repellent-protected skin site and did not bite, tried again after a short period of time and were still able to find tiny unsprayed places. Thus, it is most probable that the efficacy of repellents is mainly based on hiding the host by covering the normal skin substances that are attractive to bloodsuckers.

Efficacy Tests of Repellents

Cage Tests

In this type of trial about 1,000 mosquitoes are kept in transparent plastic cages. At the beginning of each series one hand of the test subject is sprayed with the repellent, while the other hand is left free from the product. The treated hand is then covered with a plastic glove so that about 25 cm² of the sprayed area is left free. The same is done with the hand that has not been sprayed. At

first, the unsprayed hand is held in the cage to check whether the female mosquitoes are really attracted by the non-treated skin of the test subject. After this test, the treated hand is entered into the interior of the cage for 3 min. During this period, it is observed how many mosquitoes land on the sprayed skin area and how many of the biters are starting to suck blood. If there are no bites within 3 min, the procedure is repeated at intervals of 1 h until three bites have occurred within the given period of 3 min. For example, if these three bites first occur 6 h after the spraying, the protection period of this product would be 5 h with regard to the tested mosquito species. The cage test is very important, as the conditions are especially hard because many more mosquitoes are used compared with tests in the open air and because all females are very hungry at the same time. These tests should be repeated involving as many subjects as possible, as it was found that there are broad variations among humans with regard to their attractivity for mosquitoes. However, there are no data that really prove that women or men are significantly more attractive for blood-feeders. In both sexes people have either a high or low attractivity to mosquitoes.

Field Tests

Field tests were carried out outside of buildings in biotopes with different temperatures where mosquitoes breed and seek hosts. Volunteers (either treated with a repellent or not) are placed on a chair in a selected biotope and are exposed to the female mosquitoes in their own surroundings. Four more subjects (protected by mosquito gauze) are placed around the volunteer. These subjects note how long the repellent-treated person or the untreated control person remains free from bites (Barnard 2000; US EPA 1999). On the one hand, this test system offers advantages over the cage test; however, it also has severe disadvantages. The advantages are that the test is performed under natural conditions (outside, at high or low temperatures, high or low humidity, different day time conditions, perspiration, etc.). The disadvantages of this test system are based on the fact that it is not known how many individual relevant mosquito species are in the surroundings of the test

person in the selected test area. Furthermore, it is not known, how many of the available female mosquitoes are really hungry and thus would be willing to attack a volunteer within the scheduled test period. In addition, the exact species of an attacking mosquito cannot be determined.

However, in any case, it is necessary to test a new product using the cage test in addition to the field test as often as possible. Furthermore, the field test should also be carried out in the relevant areas of all mosquito-inhabited continents, as the behavioral activities of different mosquito species (or even strains) may vary considerably in the different biotopes worldwide.

Saltidin has been successfully tested on all continents under varying climatic conditions and its long-lasting protection against many species of blood-feeding arthropods has been demonstrated.

Protection Range of Saltidin

As described in section “[Efficacy Tests of Repellents](#)” the protection period of any repellent depends on different factors such as air movements, temperature, daytime, humidity, status of the bloodsucker (whether hungry or not), etc. Its efficacy also depends on the amount of the product that has been applied to the skin. Furthermore, it is decisive which carrier is used for the repellent substance. If it is a volatile substance, the protection period will be shorter compared with products where the repellents are included in creams, oils, etc. Thus, the different formulations of each active repellent substance have to be tested to ascertain whether they release sufficient components that lead to protection from the bites of a broad spectrum of bloodsucking species. Thus, the application of sufficient repellent is important, as it was shown (Table 2) that even mosquito species of the same genus have different limits in their recognition of various compounds that are evaporated by human skin. As the data shown in Table 2 also show that mosquitoes are able to detect very small amounts of skin-derived compounds, the results obtained in field and cage tests are very reliable when seen together.

Saltidin/Icaridin, Table 3 Mean periods of protection by Saltidin from the bites of several blood-feeding arthropods. These results were obtained in cage tests (Barnard et al. 2002; Constantini and Ilboudo-Sanogo 2001; Frances et al. 2002; Mordue 1999; Nentwig 1997; Perrotey et al. 2002; Sixtl 1993; Yap et al. 1998)

Species	Country of the test	Repellency (h)
<i>Aedes aegypti</i> Yellow fever mosquito	Malaysia	6.1
<i>Aedes aegypti</i>	Malaysia	4
<i>Aedes aegypti</i>	Germany	6.8
<i>Aedes aegypti</i>	Germany	6.4
<i>Aedes aegypti</i>	Germany	7.8
<i>Aedes aegypti</i>	USA	7.3
<i>Aedes albopictus</i> Dengue fever mosquito, Tiger mosquito	China	~7
<i>Culex quinquefasciatus</i> Vector of filarial worms	Germany	8
<i>Anopheles stephensi</i> Malaria mosquito	Germany	8
<i>Anopheles dirus</i> Malaria mosquito	Malaysia	8
<i>Phlebotomus dubosqui</i> Sand fly	France	10
<i>Stomoxys calcitrans</i> Biting fly	Germany	7

Some results of the protection periods obtained when using Saltidin in cage tests are listed in Table 3. It can be seen that these blood-feeding insects are important vectors of disease agents in many countries around the globe. Variations seen in *Aedes aegypti* may depend either on the different activity of the mosquitoes tested or on strain variations.

Table 4 shows some of the representative test results obtained in worldwide field trials. These results do not differ considerably from those obtained in cage tests with regard to the length of the protection period (compare Table 3), if it is considered that in the tests listed very high concentrations of Saltidin had been used.

A big advantage of Saltidin is that it is an effective repellent not only against a very broad spectrum of blood-feeding insects, but also acts against ticks, which are the vectors of important disease agents (see Table 6), not only in the tropics, but also in many regions of Europe and the USA.

Table 5 contains results of the repellency of Saltidin against some of the important tick species. It can be seen that the increase in the Saltidin concentration increases the duration of the

Saltidin/Icaridin, Table 4 Efficacy of Saltidin against mosquitoes and simuliids (black flies) in field trials (Barnard 2000; Jeffrey et al. 2007; Johansen et al. 2003; Mordue 1999; Perrotey et al. 2002; Webb et al. 2008; WHO 2002; Yap et al. 1998)

Species	Concentration of Saltidin in the product (test substance), %	Country	Repellency (h)
<i>Aedes albopictus</i> (Tiger mosquito)	20	Malaysia	6
<i>Aedes</i> spp.	20	USA	11
<i>Culex quinquefasciatus</i>	20	Malaysia	8
<i>Culex tarsalis</i>	20	USA	11
<i>Anopheles</i> spp.	20	USA	11
<i>Anopheles gambiae</i> (Malaria mosquito)	15	Burkina Faso	8
<i>Ochlerotatus taeniorhynchus</i> (synonym <i>Aedes</i> , vector of filariae)	25	USA	5.4
<i>Verrallina lineata</i>	19.2	Australia	8–9
<i>Simulium vittatum</i> (Black flies, Simuliidae)	20	USA	9.9
<i>Culicoides impunctatus</i> (Midges)	20	WHO data	8

Saltidin/Icaridin, Table 5 Repellency of **Saltidin** (in examples of different products on the market) against ticks in Europe and in the USA (Semmler et al. 2011)

Species	Concentration of Saltidin, %	Country	Efficacy (h)
<i>Ixodes ricinus</i>	5.8 + Monk’s pepper	Germany	6–8
<i>Ixodes scapularis</i>	20	USA	14
<i>Dermacentor variabilis</i>	20	USA	14
<i>Rhipicephalus sanguineus</i>	5.8 + Monk’s pepper	Germany	6–8
<i>Dermacentor reticulatus</i>	5.8 + Monk’s pepper	Germany	6–8

protection period against common and important tick species. However, even lower concentrations of **Saltidin** give sufficient protection during longer walking tours or during work in the open air.

Bloodsuckers and Their Vectorship of Disease Agents

Blood-feeding arthropods need the blood of their hosts run their own metabolism and (as females) to be able to produce as many eggs as possible, thus guaranteeing the survival of a sufficiently large amount of offspring. Therefore, these blood feeders are obliged to take up blood at rather short intervals and are constantly hunting for suitable hosts. This is not an easy job, as most blood feeders are rather specialized with regard to their host range and often need a daily blood meal from a particular host. On the other hand, some blood-feeding species are able to survive longer periods of starvation. For example, fleas may overwinter in the empty nests of birds without feeding. Some ticks may even survive foodless periods of 1–3 years after uptake of a full blood meal. However, short-lived lice, which have a life span of only 1–3 months (depending on the species), suck blood at intervals of 2–3 h. Thus, head and pubic lice survive only for a few hours if they drop down from a host, whereas the closely related body lice may starve for 10 days. This rather short lifespan is the price these **permanent ectoparasites** pay, whereas **temporary ectoparasites**, such as bed bugs, flies, mosquitoes, fleas, ticks, mites, etc., have developed the ability to survive longer periods of starvation throughout evolution, as they have to wait for a host, often for a long time.

Temporary ectoparasites that constantly change their hosts often transmit agents of diseases (viruses, bacteria, protozoans, worms) from one host to another. This transmission may occur **mechanically** (for example, disease agents are attached at the legs or on the body surface) or by means of a **true vectorship**. The latter term means that viruses, bacteria or parasites are reproduced or proceed with development inside the blood-feeding arthropods. This ability may lead to the persistence of disease agents in some regions. They may thus initiate epidemics or even pandemics of diseases in those regions. Mosquitoes may act as definitive vectors for agents of diseases such as malaria, Yellow and Dengue fever, filariasis, etc., while flies or tabanids are mechanical vectors, as there is no development of the agents of diseases inside their bodies (Grüntzig and Mehlhorn 2010; Jensen and Mehlhorn 2009; Mehlhorn 2008; Mehlhorn and Mehlhorn 2009, 2010). These pathogens are attached at their heavy mouthparts (see Fig. 7) within tiny drops of blood and are thus transmitted after a sudden change from one host to the next.

Two groups of blood-feeding arthropods can be significantly distinguished and are described as “**vessel feeders**” and as “**pool feeders**”. The first group includes mosquitoes, with the most important genera being *Aedes* (mosquitoes of forests and plains), *Anopheles* (fever, malaria mosquito) and *Culex* (mosquitoes that often live inside houses; Figs. 5 and 6). The females of these genera inject saliva, which contains components that prevent blood coagulation, enlarge the blood vessels and act as an anesthetic. Thus, the members of this group proceed with a quick and undisturbed blood uptake via their food channel, which runs parallel to the salivary channel inside the injected

Saltidin/Icaridin,**Fig. 6** *Aedes aegypti*, females in a cage**Saltidin/Icaridin, Fig. 7** *Chrysops* sp., showing its strong, piercing mouthparts

mouthparts (Krenn and Aspöck 2012). If the mosquitoes inject this two-channel mouthpart into an artery, the pressure inside this blood vessel enhances the blood uptake, so that mosquitoes may finish their meal within a few seconds, although they often ingest more than their own body weight. This huge amount of blood is needed to produce, for example, 100 eggs within a few days.

“Pool feeders” (Figs. 7, 8, and 9), such as tabanids, black flies, midges or ticks, possess saw-like mouthparts, which make it possible to cut hollows (“pools”) into the skin (Krenn and Aspöck 2012). These pools become filled with blood, which is kept fluid by the injection of anticlotting saliva. After the blood meal a so-called haemorrhagic reaction persists for days at the biting site, first showing a central reddish-blue dot, which later enlarges because of the penetration of blood into the subcutaneous tissues (Fig. 10). A similar blood uptake is achieved by leeches (e.g., *Hirudo medicinalis*) and vampire bats (e.g., *Desmodus rotundus*), where similar saliva components are injected into the wound during their blood meal.

However, all these sophisticated blood-sucking mouthparts would have been useless during evolution, if the blood-feeding arthropods had not have developed the means to block or minimize the reaction of the “blood donors” during the blood meal.

- Thus, at first, the landing of the insect on the surface of the host and the injection of the mouthparts must occur so smoothly that the host does not notice it; otherwise, the blood feeder would be driven away.
- The potential clotting of the blood at the bite site must be avoided; otherwise, the blood uptake would be blocked inside the food channel of the mouthparts.

Saltidin/Icaridin,

Fig. 8 Female of the midge species *Culicoides obsoletus*, the vector of the bluetongue disease in ruminants

**Saltidin/Icaridin,**

Fig. 9 Scanning electron microscopy of the black fly *Simulium morsitans*, which may act as a vector of the larvae of the filarial worm *Onchocerca volvulus*, the agent of river blindness in Africa

- The vasoconstriction of the attacked blood vessel must be stopped; otherwise, the blood flow would be slow, the blood meal would last too long and the blood feeder could be detected by the host before finishing its meal.
- Finally, it would be necessary to develop ways of minimizing the quick reactions of the immune system of the host; otherwise, severe reactions (Figs. 1 and 2) would be noted by the host and the blood feeder would be driven away.

To overcome all four of these problems, the blood feeders have developed (several times independently throughout evolution) a peculiar

cocktail of saliva components that contains many compounds at the same time (Calvo et al. 2005; Cupp and Cupp 1997). However, these different compounds are mostly unknown or recent knowledge is rather poor. The examination of these components is very difficult, as they are produced often only shortly before use and the amount obtained is very low, especially in those blood-feeding species that are as tiny as midges (0.8–1.8 mm in length). Although mosquitoes and ticks are much larger (4–6 mm), their salivary glands are tiny. Thus, the amounts of saliva that can be obtained from these blood feeders for research purposes remain very small.

Saltidin/Icaridin, Fig. 10 Typical haemorrhagic reaction after a black fly bite

In spite of the difficulties of obtaining sufficient saliva for relevant investigations, components of some blood feeders have been characterized in recent times by means of molecular biological methods. However, knowledge in this area is far from being as rich as it is in the case of hirudin obtained from leeches, which is today already being produced using genetic engineering in several pharmaceutical companies for broad application in human and veterinary medicine.

With regard to the salivarian components of arthropod blood feeders, it is known that a so-called apyrase is present in black flies (simuliids) that blocks the aggregation of thrombocytes in hosts, finally preventing blood clotting. In African species of black flies (e.g., *Simulium morsitans*), which are vectors of the worm *Onchocerca volvulus* that lead to “river blindness” in humans, a component of the saliva was identified and described as simukunin (Tsujimoto et al. 2012). This protein (SV-66) belongs to the so-called Kunitz protein group and helps to

prevent blood coagulation by disturbing the activity of the factor Xa, of elastase and of cathepsin G. As a further activity, simukunin decreases inflammatory reactions at the bite site.

The saliva of mosquitoes leads to enlargement of the blood vessels of the host. This process may also occur indirectly, when the host’s body releases histamine as a bite reaction. Furthermore, this histamine initiates the transport of water into the host tissues, so that wheals appear at the bite sites that are especially large in subjects with a high allergic potential. In mosquitoes of the genera *Aedes* and *Anopheles*, which are known vectors of the agents of yellow fever, dengue fever and malaria (Amer and Mehlhorn 2006a, b, c, d; Aspöck 2010; Grüntzig and Mehlhorn 2010; Jensen and Mehlhorn 2009; Mehlhorn 2008; Webb et al. 2008), several protein families have even been detected to be involved in the avoidance of bite reactions. Thus, it is reported in the literature that long (27–30 kDa) and short (15–20 kDa) D7 proteins (e.g., hamadarin) bind host compounds such as serotonin, histamine and norepinephrine. Because of the binding of biogenic amines, their activity in processes such as the aggregation of thrombocytes or the initiation of pain are considerably disturbed. So-called lipocalines inside the salivary glands of ticks or in bloodsucking raptor bugs (e.g., *Triatoma* and *Rhodnius* species) are claimed to have similar functions, and are involved in the transmission of the protozoan parasite *Trypanosoma cruzi*, which introduced the so-called Chagas disease into humans in South and Central America.

As many other compounds of the saliva (e.g., ixolaris in ticks) disturb or even block blood clotting, these isolates may be considered to be models for new products to be used as blockers of blood clotting. Therefore, the constant and intense search for components inside the saliva of blood-feeding arthropods may offer new insights into the processes of the transmission of disease agents as a consequence of the activities of the enormous armada of bloodsuckers (Amer and Mehlhorn 2006a, b, c, d; Becker et al. 2013; Dutta et al. 2010; Grüntzig and Mehlhorn 2010; Gupta and Reddy 2013; Jansen et al. 2009; Qu and Zhu 2009; Xi et al. 2013).

At Which Developmental Stages Do Bloodsuckers Feed on Blood?

Table 6 shows the developmental stages of some important blood-feeding arthropods that suck blood. During these feeding processes, at the different stages, they may ingest the disease agents or they may transmit them via saliva (e.g., mosquitoes) or via their feces (e.g., *Triatoma* bugs).

Therefore, it is very important for an effective repellent to offer excellent, long-lasting protection against all the blood-sucking developmental stages of as many parasites as possible. Only

such a broad range of activity blocks the transmission of severe diseases (Table 1).

Importance of Protection from the Bites of Bloodsuckers

The overview by Ulrich et al. (2013) on the probability of the transmission of sporozoites of the *Plasmodium* species (agents of malaria) during the blood meal of *Anopheles* mosquitoes clearly shows that the “old” rule “no bite = no transmission” still stands today. Thus, any means of significantly preventing the bites of blood feeders is the safest protection. Therefore, protection by a safe and efficient repellent such as **Saltidin** is clearly better than the use of a poorly acting vaccine, because the use of the latter would not lead to a feeling of safety. Furthermore, there are only a few vaccines available, whereas the health of humans is threatened by a very large number of vector-transmitted diseases – often at the same time. When looking at the availability of specific medications against many agents of vector-transmitted diseases, the situation is alarming, as practically no viral diseases and many parasites can be treated using drugs. Therefore, the use of a safe repellent such as **Saltidin** is the method of choice. This is again underlined by the publication of Ulrich et al. (2013), showing that even very low rates of inoculation against disease agents (entomological inoculation rates [EIR]) of less than 1.7 (= the number of bites that a person receives in a given period) had been sufficient so that in some regions of Africa, 30–40 severe (brain) cases of malaria occurred in a group of 1,000 children within 9 months. Further studies confirmed these results and documented that higher numbers of bites led to significantly higher numbers of outbreaks of severe diseases. These consequences occur not only in the case of mosquito bites, in which it takes (depending on the temperature) several days after a blood meal before disease agents are ready to transmit again, but also in the case of ticks. For example, *Ixodes ricinus* ingest the viruses of so-called Spring–Summer encephalitis, when larvae, nymphs and adults suck blood from an infected

Saltidin/Icaridin, Table 6 List of developmental stages of examples of some of the important vectors of diseases, which suck blood (**yes**) or do not suck blood (**no**) (Aspöck 2010; Mehlhorn 2008)

host (e.g., mice), reproduce them during their molt inside their salivary glands and transmit them to another host during the next bite. The females commonly transmit these viruses to their eggs, so that the larvae of this single tick may already be transmitting the viruses within a few minutes after the attachment to their first host (including humans). This period between attachment and transmission is so short that even very quick mechanical removal of the attached tick from the skin with the help of tweezers does not prevent the transmission of these viruses (Aspöck 2010; Mehlhorn and Mehlhorn 2009; Mehlhorn et al. 2012).

The research results clearly prove that it would be life-saving in many regions of the world (Table 1) if the transmission of disease agents were drastically reduced with the help of appropriate repellents such as Saltidin. However, this product must be used correctly, which means that sufficient amounts must be sprayed onto the skin and clothes, where ectoparasites may hop on. Furthermore, thicker clothes may help to protect against mosquito bites. In any case, the use of repellents is a must in regions with a high level of vector-transmitted diseases. Finally, as all repellent products have varying protection times, usually shorter than a night, it is advised to sleep under a mosquito net impregnated with insecticides when in the tropics.

Conclusions

The present paper has shown that the health of humans worldwide is threatened by the bites of ectoparasites, because their saliva or feces may contain a broad spectrum of disease agents (viruses, bacteria, rickettsiae, protozoans, worms) that may lead to severe or lethal infections. As there are only a few effective vaccines and only a few effective chemotherapeutical remedies, the use of effective repellents such as **Saltidin** is a must in regions with a high level of vector-transmitted disease agents. As even in

more temperate regions such as Central Europe and some regions of North America, borreliosis, or tick-borne diseases, may occur alongside mosquito-derived ones, only repellents that protect against ticks and against mosquitoes at the same time should be used. Of course, the use of repellents only makes sense, if the following requirements are fulfilled by the product used:

- A long-lasting protection period.
- Ability to act against a very broad spectrum of blood feeders.
- Absolutely safe skin application.
- A pleasant scent.
- No damage to clothes, bracelets, plastic, shoes, etc.

All these requirements are fulfilled by the compound Saltidin.

Phlebotominae

Classification

Family of ► [Insects](#).

General Information

Fossil phlebotomines are about 120 million years old. Of the about 700 phlebotomine sand fly species, only about 70 are anthropophagous, mainly belonging to the two genera, ► [Lutzomyia](#) (New World) and ► [Phlebotomus](#) (Old World). Only female flies suck blood, but also – like males – they suck plant sugars, e.g., aphid honeydew, nectaries, or fruits. Phlebotomines transmit viral and bacterial diseases but are mainly known as vectors of ► [Leishmania](#).

Phlebotomines are holometabolous insects' larvae developing in the soil. Adults are small, hairy ► [Diptera](#), holding their pointed wings erect in a characteristic manner above their bodies – like a vertical V.

Distribution

Phlebotomines are found mainly in the tropics and subtropics, but some species also occur in temperate regions. There are no phlebotomines on the Pacific islands and in New Zealand. The habitats vary strongly, e.g., dry hot deserts and tropical rain forests (Figs. 1 and 2).

Morphology

The general 2.5 mm long adult flies possess long slender legs and many long slender scales on the body and wings, giving the hairy appearance. The head is elongated, possessing well-developed eyes and antennae. The mouthparts are at least as long as the head and consist of labrum and mandibles (all building the food channel), laciniae and hypopharynx, the latter containing the salivary channel. The 5-segmented maxillary palps are well developed. The pointed wings contain numerous parallel veins. Males and females cannot be separated according to antennae-like

nematoceran ► [midges](#) but by the weaker developed mouthparts of males, in which mandibles are absent and – more easily – by the long external genitalia of males. The elongated, wormlike

larvae possess a well-sclerotized head capsule with chewing mouthparts and on the following segments, rows of multibranched setae and caudal bristles which are almost as long as the body. The thoracal segments can be separated from the abdominal segments only by the ventral pseudopods of the latter. The caudal segments of the ► [pupa](#) remain in the skin of the last larval ► [instar](#).

Sand Flies, Fig. 1 Macrophoto of an adult specimen of *Phlebotomus papatasi*

Genetics

In cross-mating experiments and by morphometrics or ecological investigations, genetically distinct groups of populations have been found for some species and also sibling species.

Reproduction

Breeding of phlebotomines in the laboratory is possible for some species, but difficult.

Mating occurs on the host or nearby, and males produce pheromones and in some species “courtship songs” with their wings. In most species females are gonotrophically concordant, i.e., they require one blood meal for the development of each batch of mature eggs. However, there are also autogenic species or populations laying at

Sand Flies, Fig. 2 Adult sandfly on human skin

least the first batch of eggs without a blood meal. The number of blood meals and egg depositions determines the possibility of transmission of disease. About 3–8 days after a blood meal, eggs are laid. Females lay about 30–70 eggs (0.3 mm long and 0.1 mm wide) into soil. Breeding sites are always relatively cool and damp, e.g., rodent burrows or animal pens.

Life Cycle

After a temperature-dependent embryonic development of about 1–2 weeks, first instar larvae hatch. Larvae feed on organic detritus and its microorganisms. Since diapause occurs in species of temperate regions, and since the development is temperature-dependent, the total duration of the four larval instars varies greatly. The development of the inactive pupa usually lasts between 5 and 10 days. The pupae are very sensitive to desiccation. Adults emerge during the night, and activity is also mainly restricted to the night. After emergence, male terminalia rotate (see ► [mosquitoes](#)). Females live about 14 days. The whole developmental cycle (egg to egg) lasts about 20–50 days but up to several months in diapausing species (cf. ► [Diptera](#)/Fig. 1).

Biochemical/Molecular Data

Biochemical techniques, e.g., enzyme electrophoresis and gas chromatography of cuticular hydrocarbons and DNA probes, have been successfully used to distinguish between morphologically similar species.

Transmission

Adults rest by day in relatively cool and humid niches. Phlebotomines have a characteristic hopping flight and usually only fly short distances during the night (100–200 m), searching for hosts, resting, and breeding sites, but after a few days specimens were found about 2 km away from the place of release.

Feeding Behavior and Transmission of Disease

Phlebotomines are ► [pool feeders](#) and feed only under near calm conditions. The blood is pumped directly into the midgut. Sugar liquids are at first directed into the crop for sterilization and then into the midgut.

Sand flies transmit viruses, bacteria, and ► [Protozoa](#).

Sandfly fever (► [papataci fever](#), 3-day fever) is caused by viruses and is common during summer in the Mediterranean basin, Middle East, Pakistan/India, and Central America. These and other fever viruses are transmitted transovarially within phlebotomines.

A fever caused by *Bartonella bacilliformis* is restricted to the Andean Cordilleras.

However, phlebotomines are most widely known as vectors of *Leishmania*, causing cutaneous, mucocutaneous, or ► [visceral leishmaniasis](#).

Interaction of Vector and Parasite

Detailed data are only available for *Leishmania*, not for viral or bacterial infections. If the phlebotomine sucks blood from an infected human, ► [amastigotes](#) are ingested, which transform to the promastigote form and multiply in the lumen of the mid- and hindgut. After penetration of the ► [peritrophic membranes](#), they attach to the ► [microvilli](#) of the midgut wall. In established infections, ► [promastigotes](#) migrate to the foregut and attach there to the cuticular lining. The flagellates secrete and are embedded in a filamentous proteophosphoglycan. Finally, metacyclic promastigotes develop, which can survive in the vertebrate host. Often the diameter of the foregut is reduced or blocked by the masses of parasites.

The flagellates modify the levels of proteolytic enzymes, thereby increasing their survival rate. More conspicuous is a modification of the feeding and probing behavior. Presumably due to the masses of parasites in the foregut, blood ingestion is affected, and infected phlebotomines probe much more often than uninfected specimens. During each of these probings, *Leishmania* can be

transmitted. The parasites also seem to affect the duration of adult life.

Prophylaxis

Only special fine bed nets offer protection against the night-active phlebotomines. can be applied to bed nets and clothing. In addition, olive oil-soaked paper attracts the females which then stick to the oil and die.

Control

Residual Insecticides can be used in the house. In addition, reservoir hosts for *Leishmania* can be controlled, e.g., rodents in arid regions of the Old World and dogs in the Old and New World (cf. Insecticides, Ectoparasitocidal Drugs).

Sand Tampan

Argasid tick species (*Ornithodoros savignyi*) that is found in desert regions of Africa and Sri Lanka. These ► [ticks](#) often suck at night in such huge numbers that animals may die or become paralyzed.

Sandfly Fever: Synonyms

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This symptom of the leishmaniasis was first described in 1886 in troopers by the Austrian Army physician Alois Pick and called it “Hundskrankheit” = dog’s disease, since he saw similar symptoms in dogs. It took until 1907, when Giovanni Battista Grassi discovered in Italy the vector of the agent of the disease (first described by ► [Leishman](#) and ► [Donovan](#)).

Grassi called this sandfly *Phlebotomus pappatasi*. Since then the fever was also called Pappatasi fever, Pappataci (Papataci) fever, *Phlebotomus* fever, Dalmatia fever, Chitral fever, Karimabad fever or even Pick fever.

Sappina diploidea

Free-living 2-nucleated amoeba, the trophozoites of which live in faeces, hollows of bark of trees, small water ponds, etc., which reaches a size of $25 \mu\text{m}$. The trophozoites are able to introduce an amoeba-induced granulomatous encephalitis (► [GAE](#)) in humans.

Sappinia Species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The protozoans *S. diploidea* and *S. pedata* parasitize normally in horses. Rare cases are also found in humans.

Sapronotic Agent

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes an agent of disease, which is normally free-living but may multiply in a host and then introduce disease (e.g., ► [Naegleria fowleri](#), *Acanthamoeba* species).

Saprophagy

From Greek: *sapros* = foul, disintegrating, *phagein* = eat.

Organisms that feed dead organisms/faeces, e.g., larvae of flies are saprophagous.

Sarcocystis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *sarx* = meat, flesh; *kystos* = cyst, *sporos* = seed, capsule.

This term describes a genus of the protozoan group Apicomplexa (Sporozoa), which are now systematically included in the ► [Alveolata](#).

In the year 1843, Miescher observed, for the first time, cysts containing large numbers of banana-shaped protozoa within the muscles of mice. Until 1882, these cysts were termed Miescher's tubes ([1843](#)), Rainey's bodies, or psorosperms (Lindemann [1863](#); Ratzel [1868](#); Rivolta [1878](#)). Because of the typical localization of the cysts within the muscles, Balbiani ([1882](#))

Sarcocystis, Fig. 1 Life cycle of *Sarcocystis suihominis*. 1 Motile sporozoites hatch from the ingested sporocysts inside the intestine of the intermediate host, i.e., swine. 2 Two generations of schizonts are formed (5–6 and 12–17 days after infection) inside endothelial cells of blood vessels, giving rise to 60–100 merozoites by endodyogeny. 3 Free motile merozoites; first-generation merozoites enter other endothelial cells and form schizonts, whereas merozoites of the second generation induce formation of tissue cysts. 4 Cyst formation inside typical cells (muscle fibers, brain cells); within these cysts, the

parasites are reproduced by repeated endodyogeny leading to thousands of cyst merozoites which are situated inside chamber-like hollows. 5 When the final host (man) has eaten cyst-containing raw or insufficiently cooked meat, the cyst merozoites are set free and enter cells of the lamina propria. 6 Formation of female (macrogametes; 6.1) via gamonts (6.1; 6.2) within 14 h after infection. 7 Fusion of gametes. 8 Formation of the oocyst wall around the zygote. 9–11 Formation of two sporocysts (containing four sporozoites each) inside the host cell. The smooth oocyst wall often becomes disrupted. Thus, fully

Sarcocystis, Table 1 This summarizes some important *Sarcocystis* species, which are presented in the keyword ► *Sarcocystis* species of humans and animals (however, mainly farm or pet animals were considered there)

Sarcocystis, Fig. 3 LM of a section through muscle fibers of a mouse with many *Sarcocystis muris* cysts

Sarcocystis, Fig. 4 LM of sections through different *Sarcocystis* cysts (with different “walls”) of cattle

Sarcocystis, Fig. 5 Diagrammatic representation of the *Sarcocystis* relations of the three final hosts, humans, dogs, and cats, with respect to the intermediate hosts pig, cattle, and sheep. Species in the final hosts (from left to right): (1) *S. sui*hominis, (2) *S. bovi*hominis, (3) *S. suicanis*, (4) *S. bovic*anis, (5) *S. ovicanis*, (6) *S. bovi*felis, and (7) *S. ovifelis*. The stages inside the final hosts had previously been described as species of the genus *Isospora*

Sarcocystis, Fig. 6 *Sarcocystis* species. Diagrammatic representation of the development of *Sarcocystis* tissue cysts (e.g., *S. bovi hominis*) in fiber of the striated muscles. Apart from the species-specific variations of the primary cyst wall, this process is characteristic for all *Sarcocystis* species. After two generations of schizonts inside the wall cells of blood vessels in the omentum of intermediate hosts, one of the produced merozoites enters a muscle fiber and starts propagation as shown in the four steps (a–d). This tissue cyst formation starts about 1 month after oral uptake of sporulated oocysts from feces of the final hosts and takes about two further months until the infectious cystozoites have reached infectivity (d). During

this final stage, the cysts remain infectious eventually for years. Note that the banana-shaped cyst merozoites = cystozoites are finally situated in chamber-like hollows in their cysts. AS = amorphous substance inside the PV; CA = chamber-like hollow; GS = ground substance; HC = host cell; HM = host cell membrane; LP = limiting membrane of the parasitophorous vacuole (= origin of the primary cyst wall); MC = merozoite (= mother cell); ME = cyst merozoites = cystozoites; N = nucleus; NH = nucleus of the host cell; PA = protrusions of the limiting membrane of the PV; PV = parasitophorous vacuole; RH = remains of the host cell cytoplasm

Sarcocystis,

Fig. 7 Diagrammatic representation of the development of the primary cyst wall and the underlying ground substance of the tissue cyst (= transformed muscle fiber). In mature cysts, the primary cyst wall may form protrusions or not (**a–d**).

proposed the name Sarcosporidia. Today, such cysts have been seen in reptiles, birds, and many groups of mammals including man, monkey, and whale, such indicating a broad host range and worldwide distribution (Mehlhorn and Heydorn 1978a). The position of the Sarcosporidia within the Zoological system remained doubtful for long, since their life cycles were unknown. Electron microscopy of the cyst stages and comparison with Sporozoa led to the suggestion that there might be coccidian-like life cycles in Sarcosporidia (Sénaud 1967; Mehlhorn and Scholtyssek 1973). This suggestion was supported and stimulated by the finding of such a life cycle of *Toxoplasma gondii*, which also forms cysts and the fine structure of which was known to be very similar to that of *Sarcocystis* (Overdulse 1970; Frenkel et al. 1970; Piekarski and Witte 1970). The final proof of the coccidian-like nature of the Sarcosporidia was achieved by a

series of transmission experiments with cysts from sheep, cattle, and swine, in which a high prevalence had been reported as well as in several species of wild animals. In these experiments, the sarcocysts within the muscles of the above-mentioned three species were shown to be developmental stages of already known coccidians of man, cats, and dogs (Rommel et al. 1972; Heydorn and Rommel 1972a, b; Rommel and Heydorn 1972; Mehlhorn et al. 1974). Already in 1891, the stages in dogs, cats, and man had been described as *Isospora bigemina* (Stiles) and *I. hominis* (Railliet and Lucet) but were thought to be strictly host specific. Now it became evident that these authors had observed only the stages within the final host, whereas asexual cyst formation always took place within the muscles of the intermediate host, where they were described as sarcocysts (Fig. 1). Some important ones are listed in Table 1, and different stages are represented in

Sarcocystis, Fig. 8 Diagrammatic representation of the species-specific differentiations of the primary cyst wall in some *Sarcocystis* species. Figs. 2, 3, 4, and 5. The details of the life cycles and their important medical data are compiled in the keyword [Sarcocystis](#) species of animals and humans (Figs. 6, 7, 8, 9, and 10).

Sarcocystis, Fig. 10 Diagrammatic representation of fine structural aspects of a so-called cyst merozoite (cystozoite, endozoite) of *Sarcocystis ovifelis*. This stage was produced by endodyogeny inside the tissue cysts and reaches a length of 8–13 μm depending on the species. It is a waiting stage that becomes active as soon as the tissue cyst had been ingested by the final host (her cat). In the intestine of these hosts, these stages enter cells of the lamina propria of the intestine and transform (inside vacuoles) into male or female gamonts (see "[Sarcocystis](#)" life cycle). AM = amylopectin; C = conoid; DV = apicoplast; ER = endoplasmic reticulum; GO = Golgi apparatus; I = inclusion; MI = mitochondrion; MN = micronemes; MP = micropore (= cytostome); N = nucleus; NP = nuclear pore; NU = nucleolus; O = anterior opening of the conoid; P = anterior polar ring; PO = rhoptries; PP = posterior polar ring; R = conoidal rings

Sarcocystis calchasi

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This species which has its schizonts and tissue cysts in pigeons, and its gamo- and sporogony in raptor birds, is very pathogenic for pigeons, since extremely large numbers of tissue cysts inside muscles are produced. Pathologic effects are so severe that very high death rates occur after an infection (Fig. 1). The primary cyst wall inside the muscle fibers is smooth and is not provided with

Sarcocystis calchasi, Fig. 1 Light micrograph of tissue cysts in a pigeon

Sarcocystis calchasi, Fig. 2 (a–c) Transmission electron micrographs of sections through cyst merozoites = cystozoites, which are situated inside the cyst ground

substance (grey), which forms by septae chamber-like hollows. Nuclei are colored pink; mitochondria green

protrusions (Fig. 2a, b). The metrocytes and cystozoites (cyst merozoites) are enclosed in chamber-like hollows, which are separated from each other by thin septae consisting of amorphous material (Fig. 2b, c).

Sarcocystis corvusi

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This species was described from jackdaws (*Corvus monedula*) being closely related to *S. columbae*, *S. calchasi*, and *S. mobeseri*, which also parasitizes birds as intermediate hosts and

possesses the same smooth primary cyst wall, while *S. wenzeli* of chickens in China has clearly protruding palisades.

Sarcocystis lindemanni

In the muscles of humans, tissue-cysts were described with a size of about $120 \times 70 \mu\text{m}$ (Fig. 1). The cyst merozoites (bradyzoites) have a length of up to $13 \mu\text{m}$. The final host and the way

Sarcocystis lindemanni, Fig. 1 LM of a cross section through a human muscle fiber with a sarcocyst

of infection is unknown. Probably humans are only accidental hosts, since many species of monkeys show such cysts, which may induce myositis. This parasite apparently, has a worldwide distribution, since it was originally described by the German physician Lindemann, who, in the service of the Russian Czar, found these cysts in the tongue-muscles of hanged prisoners.

Sarcocystis nesbitti

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This species, which recently is found to parasitize more and more often humans that live in Malaysia or stayed for a longer period in Malaysia (e.g., on the island Tioman), leads to a typical *Sarcocystosis*. This is characterized by a two-phase disease. After an initial fever later follow prolonged myalgia, eosinophilia, and CK increase. The initial treatment with cotrimoxazole shortened the period of symptoms to about 20 days, while a later treatment stopped symptoms only after 3 months. Most common symptoms are weakness, fever ($38\text{--}40^\circ\text{C}$), headache, muscle and neck pain, sweating, feeling sick, and diarrhea. However, humans do not seem to be the typical intermediate host (they are probably monkeys), while the final host is still unknown.

Sarcocystis Species of Birds

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

A broad range of birds are infected with *Sarcocystis* species as can be diagnosed by the existence of tissue cysts inside their muscle fibers. With respect to transmission experiments, rather few species are investigated. Thus in many cases, the life cycle is unknown, since the final (definitive) host (a raptor animal) has not yet

been detected. The species determination in these cases is based on gene sequences in units such as 18SrRNA, 28SrRNA, or ITS-1.

The following *Sarcocystis* species have been described in more details than others:

Species	Intermediate host	Final host
<i>S. albifrons</i>	White fronted goose (<i>Anser albifrons</i>)	Arctic fox
<i>S. anasi</i>	Mallard ducks (<i>Anas</i> species)	?
<i>S. calchasi</i>	Domestic pigeon (<i>Columba livia</i>)	Hawks (<i>Accipiter gentilis</i>)
<i>S. chloropusae</i>	Moorhen (<i>Gallinula chloropus</i>)	Minks?
<i>S. columbae</i>	Wood pigeon (<i>Columba palumbus</i>)	Hawks (<i>Accipiter nisus</i>)
<i>S. cornixi</i>	Hooded crow (<i>Corvus cornix</i>)	?
<i>S. corvusi</i>	Jackdaw (<i>Corvus monedula</i>)	?
<i>S. falcatula</i>	Falcons (<i>Falco</i> sp.)	?
<i>S. lari</i>	Black-headed gull (<i>Larus marinus</i>)	?
<i>S. neurona</i>	Brown-headed cowbirds (<i>Molothrus ater</i>)	?
<i>S. ramphastos</i>	Red-billed toucan (<i>Ramphastos sulfuratus</i>)	?
<i>S. rileyi</i>	Mallard duck (<i>Anas platyrhynchos</i>)	Striped skunk (USA)
<i>S. spec</i>	Golden eye (<i>Bucephala clangula</i>)	?
<i>S. sulfuratusi</i>	Red-billed toucan (<i>Ramphastos sulfuratus</i>)	?
<i>S. turdusi</i>	Common blackbird (<i>Turdus merula</i>)	?
<i>S. wobeseri</i>	Barnacle goose, Mallard duck (<i>Anas platyrhynchos</i>)	?

Sarcocystis Species: Animals as Final Hosts

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Sarcocystis Species of Cats and Dogs

Name

Greek; *sarx* = meat, flesh; *sporos* = seeds. The species names consist of a combination of the names of intermediate and final hosts.

Geographic Distribution/Epidemiology

The species occur worldwide, and the prevalence rates reach often up to 40 % especially on farms with numerous animals and close contacts between final and intermediate hosts.

Morphology/Life Cycle

Cats and dogs are as predator final hosts of a broad series of *Sarcocystis* species (see Table 1, “► *Sarcocystis*”). However, the oocysts and sporocysts, which are formed inside these final hosts, cannot be distinguished from each other by microscopic investigations but only by molecular biological criteria. However, the morphologic features of their cyst stages (initiated inside the plant-eating or omnivorous intermediate hosts) can be used as criteria to differentiate between

species. The following main species are proven to occur in the intestines of dogs and cats and of course in the intestines of relatives of these two host types. Some combinations of these hosts are represented in Fig. 1.

A. Dogs:

1. *S.bovicanis* (cysts in cattle)
2. *S.ovicanis* (cysts in sheep)
3. *S.arieticanis* (cysts in sheep)
4. *S.equicanis* (cysts in horse)
5. *S.capracanis* (cysts in goats)
6. *S.hircicanis* (cysts in goats)
7. *S.suicanis* (cysts in pig)

B. Cats:

1. *S. bovisfelis* (cysts in cattle)
2. *S. ovifelis* (cysts in sheep)
3. *S. muris* (cysts in mouse)
4. *S. cuniculi* (cysts in rabbit)
5. *S. cymruensis* (cysts in rat)

The development of the sexual stages (gamogony) and the formation of the oocysts inclusive of the typical formation of the two sporocysts and their four sporozoites occur in the cells of the lamina propria of the intestine (= the layer just below the epithelial cells). However, asexual reproduction phases (= schizogony) do not occur before gamogony starts. This means that the cystozoites (i.e., cystmerozoites; Fig. 1) are transformed directly into male or female gamonts. The fully sporulated oocysts (12–18 $\mu\text{m} \times 8\text{--}12 \mu\text{m}$) are set free after rupture of their host cell and become excreted within the feces of dogs and cats. After oral uptake of sporocysts, the hatching sporozoites lead to the formation of two generations of schizonts inside cells of omentum blood vessels of intermediate hosts. The second generation of merozoites leaves (about 30 days after oocysts had been ingested by the intermediate host) the blood vessels and starts cyst formation in muscles, brain, etc. (Fig. 1). In the time before the *Sarcocystis* life cycles had been detected, the oocysts excreted by cats and dogs had been described by the name *Isospora bigemina* referring that these oocysts contain two similarly looking sporocysts (= double seater).

Symptoms of Disease

In the final hosts (cats, dogs) symptoms of the infestation by *Sarcocystis* species are described as “coccidiosis.” This general term refers to the leading symptoms of diarrhea, if at all it occurs, since probably most cats and dogs do not show symptoms of disease.

Diagnosis

Microscopic inspection of oocysts and sporocysts after use of concentration methods such as ► [flo-tation](#), ► [S.A.F.C.](#), ► [M.I.F.C.](#)

Infection

Dogs and cats are infected by oral uptake of tissue cysts of the *Sarcocystis* species within raw or undercooked meat of infected intermediate hosts.

Prophylaxis

Cats and dogs should only be fed by deep frozen food or fully cooked meat. Since *Sarcocystis* oocysts excreted by dogs and cats may infect intermediate hosts on farms etc., resting places/cages of dogs/cats should be cleaned by hot steam in order to destroy oocysts and sporocysts.

Incubation Period

One to two days (final hosts), 3–4 weeks (intermediate hosts).

Prepatent Period

Eight to ten days (dogs), 5–14 days (cats).

Patency

Six to seven weeks.

Therapy

In cases of dogs and cats, treatment is normally not needed due to unremarkable symptoms. In the occurrence of diarrheas, application of coccidiostatica is recommended.

Sarcocystis Species in Ruminants

Name

Greek – *sarx* = meat, flesh; *sporos* = seed, cyst.

Sarcocystis Species: Animals as Intermediate Hosts, Fig. 1

Light micrographs of schizonts of *S. arieticanis* inside epithelial cells of blood vessels of sheep. *BGF* blood vessels, *BL* basal lamina, *E* erythrocyte, *EP* epithelial cell, *GW* wall of blood vessel, *ME* merozoite, *NH* nucleus of the host cell, *SC* schizonts

Species names are composed of names of intermediate and final host species (e.g., *bovicanis* – Latin: *bos* = cattle; *canis* = dog).

Geographic Distribution/Epidemiology

Worldwide, high prevalence rates (occasionally of 50 %) in animals on meadows.

Morphology/Life Cycle

After ingestion of sporulated oocysts, two generations of schizonts occur in cells of the wall of blood vessels of the omentum (Fig. 1). Beginning after one month cyst formation starts in muscle cells (Fig. 2). The formerly as Miescher's tubes (Miescher) described tissue cysts can be found as different species in all ruminants. The following species (see others in Table 1, ► [Sarcocystis](#)) are of importance for humans, since they may infect

Fig. 5 Light micrograph of a section through a *S. ovicanis* cyst of sheep

***Sarcocystis* Species: Animals as Intermediate Hosts,**
Fig. 6 Light micrograph of a section through a *S. arieticanis* cyst of sheep

Inside the intermediate hosts, first a schizogonic reproduction occurs. Within parasitophorous vacuoles inside the endothelial cells, two generations of schizonts occur during the first month after the infection (Fig. 1). Beginning about 30–40 days after the infection, merozoites of the second generation enter muscle fibers and start to form tissue cysts, which need about two more months in order to develop infectious

cystozoites (or cysts merozoites) (Fig. 2). These tissue cysts remain infectious for more than one year for final hosts (predators), where gamagony and sporogony run inside the cells of the lamina propria of the intestine.

Symptoms of Disease

Only those species, where the oocysts are formed inside dogs or carnivores, are significantly

**Sarcocystis Species:

Animals as Intermediate
Hosts, Fig. 8** Two brother
pigs. The *right* one was
experimentally infected
with *S. suicanis*. Note the
considerable loss of weight
(or reduced weight gain)

pathogenic. During the phase of endothelial schizogony, the following symptoms occur: apathy, high fevers, anemia, icterus, hemorrhages, and swellings of lymph nodes, the liver, and the spleen, as well as edemas on the skin (e.g., of ears, Figs. 7 and 8). In very severe infections also fatal cases may occur; however, this depends on the amount of ingested sporocysts, since each of the sporozoites may form a schizont with 50–80 first stage merozoites, which each again produces 40–80 stage merozoites. After survival of such an acute phase of **sarcocystosis**, a specific immunity is obtained. However, the period of persistence is not yet known. Therefore, reinfections remain mostly insignificant.

Diagnosis

During the acute phase (1st month) diagnosis is very difficult, since the merozoites occur only in scarce numbers within the peripheral blood (for microscopic smear preparation). During the cyst phase (starting from day 30–40 p.i.) biopsies of muscles followed by trypsin digestion will show cyst merozoites, if the infection rate is not too low. However, during this phase serologic tests (ELISA, IFAT) produce reliable results.

Infection

Oral uptake of sporocysts (oocysts) excreted by final hosts.

Prophylaxis

Avoid contact of dogs to animals on the meadow; do not feed raw meat to dogs.

Incubation Period

Eleven to twelve days = duration period on the first generation of schizont formation.

Prepatent Period

About 12–14 days.

Patency

Eventually 1 year or even longer.

Therapy

There are not very well proven treatment schemes. However, since the phases of schizogony (1st month) are the most dangerous ones of the life cycle, it might be needed to try to control the formation of schizonts by means of amprolium (e.g., Amprovet®) (100 mg per kg bodyweight) in the case of cattle. An oral treatment with toltrazuril (10 mg/kg bodyweight on day 5, 10, 15, 20, and 25 p.i.) was also successful. In the case of cattle, goats, and sheep, halofuginone hydrobromide (Stenorol®) was actively tested by Heydorn (Berlin) to cure the schizogony of *Sarcocystis* schizonts when given in dosages of 0.66 mg/kg bodyweight on two consecutive days.

Sarcocystis Species of Horses and Other Equids**Name**

Latin – *equus* = horse; *canis* = dog; *neurona* = infects nerves.

The species name *bertrami* honors the author (Bertram) of the first description.

Geographic Distribution/Epidemiology

Worldwide, epidemics may occur among stressed or very young horses.

Morphology/Life Cycle

1. *S. bertrami*: The cysts are macroscopically visible (reach up to 15 mm in length and are provided with hairlike protrusions). Final

hosts are not yet definitively proven in experimental transmissions.

2. *S. equicanis*: The tissue cysts are microscopically small reaching a size of only $600 \times 50 \mu\text{m}$. The protrusions of the tissue cysts at first stand upright, but later when grown up and reaching 5–11 μm in length, they lay parallel to the cyst's surface, so that the cysts then appear thin walled. Final hosts are dogs and other canids, which start on day 8 p.i. with the excretion of $15 \times 10 \mu\text{m}$ -sized sporocysts for at least 21 days. Two generations of schizonts are formed within the muscle fibers of horses during the first 30 days after oral uptake of sporocysts excreted by dogs. These tissue cysts contain after 60–90 days infectious cyst merozoites.
3. *S. neurona*: This species is not finally proven as a definitive species, since mainly stages (reproducing by endodyogeny) are demonstrated in the brain of some horses in the USA. Tissue cysts are not yet found. Opossums were claimed to be final hosts.

Symptoms of Disease

In general horses show no or low-graded symptoms after an infection with *S. bertrami* or *S. equicanis*, although occasionally myositis and disturbances of movements have been described. However, in the case of *S. neurona*, equine protozoal myeloencephalitis (► [EPM = disease](#)) was apparently present in all cases of brain infections after.

Diagnosis

Squeezed preparations of muscle fibers will show cyst stages in the light microscope or muscle probes after being digested by the help of trypsin.

Infection

Oral uptake of oocysts/sporocysts from the feces of the final hosts.

Prophylaxis

Keep away dogs from horse stables and meadows.

Incubation Period

Months.

Prepatent Period

Cysts can be found about 30–40 days p.i. in the muscles of horses, unknown in *S. neurona*.

Patency

Years.

Therapy

Not really tested; trials should be done with products used for cattle in cases where symptoms are seen.

appears thick walled, since the 4.8 μm long protrusions of the primary cyst wall stand upright.

Both species proceed in the intermediate host (pigs) for about 1 month a phase of schizogony (2 generations) inside blood vessels of the omentum and start around the 30th day p.i. with the formation of tissue cysts in muscle fibers.

Symptoms of Disease

The intensity of the disease depends on the amount of ingested oocysts (one million leads to death). Acute sarcocystosis (which is introduced by schizogony inside endothelial cells of blood vessels of pigs on days 5 and 19 as well 11–15) shows significant fevers, apathy, dyspnea, anemia, and eventually death. A cyanotic color of the skin of the ears (Fig. 7), the tail, and other parts is characteristic.

Diagnosis

Biopsies after day 30 p.i. show the cystozoites (Fig. 9). However, in low-graded infections serologic results are obtained when using serologic tests (e.g., IFAT, IHA, ELISA) – especially during the phase when tissue cysts are already present in the muscles.

Infection

Oral uptake of sporocysts within feces of dogs (*S. suicanis*) or humans (*S. suihominis*).

Prophylaxis

Farmed pigs should not have contact to feces of dogs or humans. Dogs should not be fed with raw meat.

Incubation Period

About 5 days.

Prepatent Period

About 1 month until the tissue cysts are formed.

Patent Period

At least 1 year.

Sarcocystis Species of Pigs and Boars**Name**

Species names represent a combination of the Latin names of final and intermediate hosts (*homo* = human; *sus* = pig; *canis* = dog).

Geographic Distribution/Epidemiology

Worldwide, heavy infections may introduce considerable economic losses in farmed intermediate hosts.

Morphology/Life Cycle

In pigs two species of the genus *Sarcocystis* have been demonstrated:

1. *S. suihominis*: Final hosts are humans, who excrete oocysts and sporocysts within their feces. Tissue cysts in the muscles of pigs reach a length of up to 5 mm. They are found in cells of all types of muscles as well as in brain cells. The cysts appear thin walled in light microscopy. Electron microscopic studies showed that the protrusions of the primary cyst wall are up to 14 μm long but lay parallel to the surface. The interior of the cyst shows as other typical *Sarcocystis* species chamber-like hollows filled with merozoites (in chambers at the periphery) and cyst merozoites (cystozoites), which reach a length of up to 16 μm .
2. *S. suicanis* (syn. *S. miescheriana*): Final hosts are dogs and other canids. The tissue cysts reach a length of 1.5 mm and are found in the heart and skeletal muscles. The cyst wall

Sarcocystis Species: Animals as Intermediate Hosts, Fig. 9 Light (a) and scanning electron microscopic photos of cystozoites (cyst merozoites) in Giemsa-stained smear preparation (b) and in chambers of a tissue cyst

Therapy

Not tested; however, trials with toltrazuril seem useful.

Sarcocystis Species of Birds

Name

The species name *horvathi* honors the Hungarian scientist Horvath as first describer of this species; in Latin, *falcatula* was given since at first it was thought that falcons are the final host of this species. The Greek name *calchasi* honors/remembers the Greek prophet Kalchas, who dreamed of a hawk during the so-called Trojan War. This predator bird killed a dove by the help of a trick. The hawk first hid itself and then attacked the inattentive dove from its hideout. Kalchas advised the Greek aggressors to do the same. The Greek left the shore and left back the Trojan horse with warriors in its interior, and the inattentive Trojans transported the “poisonous gift” into their town thus designing their fate.

Geographic Distribution/Epidemiology

Worldwide with high prevalence rates among farmed birds.

Morphology/Life Cycle

In the muscles of chickens, at least two species of the genus *Sarcocystis* occur (*S. horvathi* and *S.*

sp. = unnamed; see Table 1). The tissue cysts of *S. horvathi* are found in the muscles of the domestic chickens and possess 3 µm long protrusions at their surface. In canary birds and in doves, *S. falculata* cysts are found. As final hosts opossums are involved in the propagation of this species. Also further *Sarcocystis* species may occur in doves and other birds (Table 1). For example, in the case of *S. calchasi*, tissue cysts occur in the muscles of doves and northern goshawks are the final hosts (Figs. 10 and 11). Severe infections induce loss of flight capacity or even death since due to their immobility they are unable to find food.

Diagnosis

Postmortem inspection of infected prey birds shows tissue cysts within muscle fibers (Figs. 11 and 12). Feces control of predator birds showed oocysts or sporocysts of typical *Sarcocystis* species.

Infection

Oral uptake of oocysts excreted by predator birds.

Prophylaxis

Protect farmed chicken from feces of predator birds.

 nucleus

S

Incubation Period

Two to eight weeks are needed (in case of experimental infections) to obtain clinical symptoms in intermediate hosts.

Patency

The tissue cysts start to degenerate after 4 months.

Prepatent Period

It takes at least 4 weeks until tissue cysts become visible in muscles.

Therapy

Unknown.

Sarcocystis Species: Humans as Final Hosts

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

*Sarcocystis sui*hominis and *S. bovi*hominis

Name

Greek: *sarx* = meat, flesh; *kystos* = cyst. Latin: *sus* = porc, pig; *homo* = human; *bos* = cattle; Miescher's tubes = long cysts in muscle fibers detected by the swiss scientist Miescher (1811–1887).

Geographic Distribution/Epidemiology

Worldwide, probably several hundred million humans are infected from time to time. However, only rather few show clear significant symptoms for a short period of 24 h after an infection.

Morphology/Life Cycle

Infections occur with *S. sui*hominis and *S. bovi*hominis, if humans eat raw or undercooked meat of pigs respectively cattle that contains tissue cysts of these two species (Figs. 1, 2, 3, and 4). These cysts contain cystozoites (Fig. 4) and are characterized by different types of protrusions of the primary cyst wall. In the intestine of humans the cystozoites are set free and enter the intestinal wall. Inside the cells of subepithelial layer (lamina propria) gamogony starts and gives finally rise to fully sporulated oocysts of 20–25 $\mu\text{m} \times 12\text{--}15 \mu\text{m}$ in size (Fig. 5), which contain two sporocysts and possess only a very thin oocyst wall. This wall ruptures easily so that in the stool of humans mostly $14 \times 8 \mu\text{m}$ sized sporocysts (containing each 4 sporozoites) are found (Figs. 1 and 5). This development from infection until excretion of first oocysts takes 5–7 days.

Symptoms of Disease

The disease is called **sarcosporidiosis**, **sarcocystosis**, or respectively **coccidiosis** and starts about 4–6 h after ingestion of raw or undercooked meat containing tissue cysts. The intensity of the symptoms depends on the number of ingested parasites, since each of them enters an intestinal cell and destroys it during gamogony and sporogony (Fig. 1). *S. sui*hominis is considerably more pathogenic than *S. bovi*hominis. The initial symptoms are sweating and ague, which are followed for 4–24 h by vomiting, diarrheas at short intervals, and intestinal colics. The intensive loss of water due to numerous defecations disturbs

Sarcocystis Species: Humans as Final Hosts, Fig. 1

Diagrammatic representation of the life cycle of *Sarcocystis suis hominis*. (1) Motile sporozoites hatch from the ingested sporocysts inside the intestine of the intermediate host, i.e., swine. (2) Two generations of schizonts are formed (5–6 and 12–17 days after infection) inside endothelial cells of blood vessels, giving rise to 60–100 merozoites by endopolygeny. (3) Free motile merozoites; first-generation merozoites enter other endothelial cells and form schizonts, whereas merozoites of the second generation induce formation of tissue-cysts. (4) Cyst formation inside typical cells (muscle fibers, brain cells); within these cysts the parasites are reproduced by repeated endodyogeny leading of thousands of cyst merozoites which are situated inside chamber-like hollows. (5) When

the final host man has eaten cyst containing raw or insufficiently cooked meat, the cyst merozoites are set free and enter cells of the lamina propria. (6) Formation of female (macrogametes; 6.1) via gamonts (6.1; 6.2) within 14 h after infection. (7) Fusion of gametes. (8) Formation of the oocyst wall around the zygote. (9–11) Formation of 2 sporocysts (containing 4 sporozoites each) inside the host cells. The smooth oocyst wall often becomes disrupted. Thus, fully sporulated oocysts are found in the feces (11). DM developing merozoites, DR disrupted oocysts wall, HC host cell, N nucleus, NH nucleus of the host cell, OW oocysts wall, PC primary cyst wall, PV parasitophorous vacuole, RB residual body, S sporocyst, SP sporozoite, WB oocysts wall-forming bodies

considerably the balance of the electrolytic system of the body, so that collapses may occur, if water is not ingested in considerable amounts. Depending on the stability of the infected persons low-graded symptoms disappear after 24 h.

Diagnosis

Demonstration of oocysts and sporocysts (Fig. 4) within the stool by help of ► [flotation](#).

Infection

By oral uptake of raw or undercooked meat containing tissue cysts of *S. bovi hominis* or *S. suis hominis*.

Prophylaxis

Avoid eating raw or undercooked meat.

Incubation Period

4–8 h.

Prepatent Period

5–10 day.

Patency

6–8 weeks.

Therapy

A specific chemotherapy is not needed, but in cases of -high-graded symptoms replacement of water loss by infusions of electrolytes may become necessary.

Sarcocystis Species: Humans as Intermediate Hosts

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Sarcocystis lindemanni

Name

From the Greek word *sarx* meaning meat and flesh and *kystos* meaning cyst. The species name honors the German physician C. Lindemann, who – in the service of the Russian Emperor – described in 1863 tissue cysts in the muscles of humans.

Geographic Distribution/Epidemiology

Worldwide; similar looking tissue cysts occur mostly in small numbers (Fig. 1) in the muscles of humans and monkeys.

Morphology/Life Cycle

After the first description in the year 1863 by Lindemann in Russia, these typical *Sarcocystis* tissue cysts were found in the muscle fibers of humans and monkeys. These cysts (Fig. 1) had diameters of 120×70 µm and were limited by a smooth ► **primary cyst** wall inside their host cells. The cyst merozoites reached about 9–15 µm in length and were situated inside chamber-like spaces within these cysts, which is a characteristic of the genus *Sarcocystis*. However, since the walls of the chamber-like compartments were very thin in this species, they are mostly only visible by electron microscopy. The life cycle and the pathway of human infections are not solved. However, it is probable that humans might become erroneously infected as an intermediate host replacing monkeys, which are often found to be infected. Thus the normal cycle of this species would run between a predator feeding – at least occasionally – monkeys or other animals, which get in nature in contact with oocysts/sporocysts in the feces of this unknown predator species.

Symptoms of Disease

In cases of human infections, swellings in the subcutaneous regions, muscle pain, and spasms have been reported to occur repeatedly over years. These symptoms were mostly accompanied by

***Sarcocystis* Species:**
Humans as Intermediate
Hosts, Fig. 1 Micrograph
 of a section through a
 muscle fiber containing a
Sarcocystis cyst (type
S. lindemanni)

slight fever and phases of high eosinophilia. However, only a few cases had been diagnosed by direct biopsies, but mainly occasionally during postmortem investigations.

Diagnosis

Occurrence of tissue cysts in sectioned muscle fibers (Fig. 1).

Infection

Pathway unknown, however, it occurs very probable by oral uptake of oocysts and sporocysts in food contaminated by feces of the final host (a predator).

Prophylaxis

General hygienic measurements and avoidance of eating of potentially fecally contaminated food (e.g., unwashed plants).

Incubation Period

Unknown.

Prepatent Period

Probably 2–3 months as in other *Sarcocystis* species.

Patency

At least 1–2 years.

Therapy

Unknown, probably sulfonamides will be helpful.

Sarcocystis suihominis

Life Cycle

- [Sarcocystis](#), Fig. 1.

Disease

- [Sarcosporidiosis](#), [Man](#).

Sarcomastigophora

Name

Greek: *sarx*, *sarcos* = meat, *mastix* = flagellum, *phorein* = transporting.

Classification

Phylum of ► [Protozoa](#).

General Information

Important characteristics of this group are: locomotion with ► [pseudopodia](#), ► [flagella](#) or both; sexuality, when present, essentially ► [syngamy](#); single type of nucleus.

System

The Sarcomastigophora unite the former taxa ► [Flagellata](#) and ► [Rhizopoda](#), since it has been shown that numerous species may form pseudopods as well as flagella, depending on external influences. The phylum is subdivided as follows:

- Subphylum: ► [Mastigophora](#)
- Class: Phytomastigophorea
- Class: Zoomastigophorea
- Subphylum: ► [Opalinata](#)
- Class: Opalinatea
- Subphylum: Sarcodina
- Class: Lobosea and 10 other classes

Sarconema

Name

Greek: *sarx* = meat, *nema* = filament.

General Information

This term has two meanings:

1. Synonym of toxonema and micronema, which are small ovoid inclusions in the apical region of motile stages of ► [Coccidia](#) (merozoites, sporozoites, tachyzoites). Sarconema are the structures in the relevant stages of ► [Sarcocystis](#) stages.

2. Genus of nematodes of the family Onchocercidae in the myocard and walls of blood vessels of birds. These parasites are transmitted by ► [Mallophaga](#). The sheathed microfilariae are rather short (120 µm) and are found in the blood. ► [Sarconema erycerca](#) was found in swans, goose, ducks in USA, Europe, and Russia. Vector is the feather-eating mallophag louse *Trinoton anserinum*.

Sarconema erycerca

Species of filariae (family Onchocercidae), which is found in the heart muscle of swan, goose, ducks in the USA, Europe, Russia, transmitted by ► [Mallophaga](#) (*Trinoton anserinum*). The microfilariae occur in the blood.

Sarcophaga

Name

Greek: *sarx* = meat, *phagein* = feeding (the larvae feed meat of dead bodies).

Classification

Genus of the so-called flesh flies.

Sarcophaga, Fig. 1 Adult female fly licking at sugar

Sarcophaga, Fig. 2 DR of an adult from dorsal

Sarcophaga, Fig. 3 Larval stage

Morphology

The European (holarctic) species *S. carnaria* (grey flesh fly) reaches a length of 10–14 mm (Figs. 1 and 2); the same size as the worldwide

occurring species *S. haemorrhoidalis*. The females are viviparous and place the L₁ directly onto dead or motionless bodies (e.g., drunk people). The larvae (Fig. 3) feed on meat, while the adults lick plant fluids/juices. ► [Diptera](#).

Sarcoptes

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *sarx*, *sarcos* = meat, *koptein* = beat, cut.

Classification

Genus of mites.

Important Species

See Table 1.

Life Cycle

The life cycle stages are shown in Figs. 1, 2, 3, and 4 and ► [Mites](#)/Fig. 2. Due to rather recent results *Sarcoptes cuniculi* is a synonym of *S. canis*, since this species leads to true mange in rabbits, too. In humans, *S. canis* introduces a scab-itch.

Diseases

Sarcoptes Mange (Acariosis, Animals),
► [Scabies](#).

Sarcoptes, Table 1 Important species of the genus *Sarcoptes*

Species	Length (mm)	Hosts/habitat	Disease
<i>Sarcoptes scabiei</i>	f 0.3–0.45/m 0.2–0.3	Humans/epidermis	Scabies
<i>S. bovis</i>	f 0.3–0.5/m 0.2–0.3	Cattle/epidermis	Mange

Treatment

Since most anti-mite skin cremes have only poor efficacy, it is recommended to use ivermectin (e.g., Stromectol® – registered in France).

Sarcoptidae

Family of ► [Acarina](#), comprising mites of the genera *Sarcoptes*, *Notoedres*, *Trixacarus*.

Sarcosporidia

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *sarx* = meat, flesh; *sporas* = spore, seed.

This group of protozoan parasites was described first by the Swiss biologist and physician ► [Miescher-His](#), who detected 9 µm sized (in length), bended cells in “cyst-like” inclusions in muscles of mice (Fig. 1). Since these cells did not start movements when placed in aqueous

physiological solutions, Miescher named them as spores. Since these “spores” occurred inside muscle fibers, this group thus was described with the Greek-derived term “sarcosporidia.” The single cysts in such a muscle fiber were also named “Miescher’s tubes” honoring their discoverer. Later in the years 1972–1975 the life cycles of the ► [Sarcocystis](#) species were detected by the German groups of Rommel, Heydorn, and Mehlhorn showing that these life cycles combine an intermediate host containing the tissue cysts and a final host, which excretes infectious oocysts. Today about 200 ► [Sarcocystis](#) species are known.

Sarcosporidiosis, Animals

Animals are hosts of ► [Sarcocystis](#) spp. in different ways.

1. Predator animals (= carnivorous species) like dogs, cats, reptiles, predator birds, etc. develop the sexual and sporogonic stages in their intestinal cells (lamina propria) and excrete the fully sporulated oocysts (Sarcosporidiasis, Man, Fig. 1) containing 2 sporocysts (each with 4 sporozoites). In general the predator animals do not show symptoms of disease. Sometimes diarrhoea occurs for one day with abdominal pain.

Sarcosporidia,

Fig. 1 Miescher’s tubes = *Sarcocystis muris* cyst in the muscles of a mouse. This aspect had Miescher in the day of the detection of these tissue cysts

Sarcosporidiosis, Animals, Fig. 1 LM of a thin-walled cyst in the muscles of a dove, which lost complete ability to fly and other movements due to infection of muscles and brain

Sarcosporidiosis, Animals, Fig. 3 Thick-walled cyst (*Sarcocystis ovifelis*). SEM of the periphery showing the packages of infectious bradyzoites

Sarcosporidiosis, Animals, Fig. 2 TEM of a thin-walled cyst in the muscles of a dove

Sarcosporidiosis, Animals, Fig. 4 Thick-walled cyst (*Sarcocystis ovifelis*). SEM of a bradyzoite; note the coiled arrangement of the sub-pellicular microtubules of the apical pole

- Prey animals (= plant eater or omnivorous species) are the hosts for the schizogonic phase of the life cycle with schizonts in the endothelial cells of inner organs and later with ► [tissue-cysts](#) in muscle fibres (Figs. 1, 2, 3, 4, 5, and 6, pages 1269–1272) and (in some species) in brain cells (e.g., in *S. suicanis* and *S. sui hominis* in the case of pigs). The symptoms and their intensity is species-specific. Acute symptoms may occur during schizogony in the blood vessels of the

omentum (with 2 penetrations of schizonts) due to inner bleedings: fever, apathy, dyspnoea, anaemia. Even death may be the consequence. As soon as (after about 1 month) the phase of the formation of tissue-cysts has been reached,

Sarcosporidiosis, Animals, Fig. 5 Oesophagus of sheep infected with cysts of *Sarcocystis ovifelis*

Sarcosporidiosis, Animals, Fig. 6 Two brother-pigs of same age; the smaller one is infected with *Sarcocystis suicanis*

mostly low-graded symptoms are shown, if the number of cysts is not too high. Only in a few cases generalized myositis is seen (Figs. 1 and 2).

3. A special case is the so-called Equine-Protozoal-Myeloencephalitis (EPM) in horses. This encephalitis, which occurs as final symptom of a spectrum of diseases, may also be induced due to infection with the oocysts of *S. neurona*, which are excreted by opossums (*Didelphis* spp.) in North America. In horses no cysts are found, but only the division of sarcosporidian endozoites (= tachyzoites) in brain cells. EPM-like symptoms due to infections with *S. neurona* are found also in cats, sea lions,

racoons, etc. Brains of pigs, when heavily infected with *S. suis* or *S. suicanis* may show EPM-like degenerations, too.

Diagnosis

1. In carnivores: Microscopy of faecal samples shows oocysts (Sarcosporidiosis, Man, Fig. 1).
2. In plant eaters and omnivores: Microscopy of biopsies of muscle fibres (starting 1 month after infection) shows cysts (Figs. 1, 2, 3, and 4), PCR-techniques.

Therapy

In cases of sarcosporidiasis of the endothelial cells and of cysts in the muscle the application of ► [Toltrazuril](#) was successful.

Sarcosporidiosis, Man

Pathology

Intestine

► *Sarcocystis suis* and *S. bovis* are ingested as ► [bradyzoites](#) from cysts in infected pork and beef (► [Pathology](#), Figs. 7, 8, and 9). There is no ► [schizogony](#) in the human gut. The ingested bradyzoites develop directly into gametocytes in the lamina propria; then fertilization occurs, followed by development of a ► [zygote](#) and an ► [oocyst](#). ► [Sporulation](#) takes place in the gut wall, with 2 sporocysts, each forming 4 sporozoites. Judging from a few isolated observations, where, however, the possibility of the presence of other pathogen could not be excluded, there may be intense mixed inflammatory reaction that includes eosinophils. Experimental infections suggest the absence of a strong immune reaction, and the possible hypersensitivity reactions, resulting in the greater pathogenicity of *S. suis* than of *S. bovis*. Sporulated

sporocysts are usually shed in the feces and appear to be infectious only to pigs (*S. suis*) or cattle (*S. bovis*). In older references these 2 organisms were not distinguished and identified as *Isospora hominis*. The ► [Sarcocystis](#) stages found in human muscle result from infection with different species.

Muscle

Sarcocysts different from those in the intestine are diagnosed occasionally in the myocardium and skeletal muscle of humans (► [Pathology](#), Fig. 7) who are accidental intermediate hosts for sarcocysts normally found in monkeys and possibly cattle. Mammalian, avian, or reptilian carnivores may be the definitive hosts ingesting bradyzoites in cysts and shedding oocysts in their feces which are accidentally ingested by humans. Intact cysts with bradyzoites measuring up to 100 µm in diameter and 325 µm in length and unaccompanied by inflammation are the usual findings (► [Protozoan Infections, Man](#), Table 1). However, cases with young cysts and diffuse lymphocytic and eosinophilic infiltration have been described, probably from recent infections. Whether the inflammation is a consequence of the prior schizogony in blood vessels, or of young cysts that degenerate, or both, has not been determined. Evidence of lesions from cyst rupture has been reported, where an eosinophilic myositis with lymphocytes, and later fibrosis, was diagnosed by biopsy of one of a number of suddenly appearing spontaneous lesions. These events occurring over many years, were accompanied by painful muscle swelling, initially associated with ► [erythema](#) and occasionally with bronchospasm, and lasted for 2 days to 2 weeks.

Intestinal sarcosporidiosis

Main clinical symptoms: ► [Vomiting](#), sweating, ► [diarrhoea](#).

Incubation period: 4–8 h.

Prepatent period: 5–10 days.

Patent period: 6–8 weeks.

Sarcosporidiosis, Man, Fig. 1 LM of two complete oocysts and a free sporocyst of *Sarcocystis bovis*

Diagnosis: Microscopic determination of sporocysts in fecal samples. (Fig. 1, page 1273).

Prophylaxis: Avoid eating raw meat of pork or cattle.

Therapy: Treatment see ► [Coccidiocidal Drugs](#) and ► [Drugs Against Sarcocystosis](#).

Sarcotaces

Genus of crustaceans, the species of which form cysts in muscles of fish.

Sauronyssus saurorum

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Blood sucking mite of lizards.

Sausage Stage

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes the transformed microfilaria (larva 1 of *Filariae*) inside the intestine of blood sucking mosquitoes just before penetration into the body cavity.

SBP-1

A parasite protein associated with ► [Maurer's clefts](#) in the *Plasmodium*-infected cytosol of red blood cells, which is involved in trafficking the Pfeme-1.

SBV

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This abbreviation describes the so-called ► [Schmallenberg virus](#), which is transmitted by bites of midges.

Scabies

Scabies is a human infection of the skin with the mite *Sarcoptes scabiei* or a transitory infection with similar species from animals where they produce mange (Figs. 1 and 2). The entire life cycle of the mite takes place in the keratinaceous layer of the epidermis which often undergoes ► [hyperplasia](#) with marked hyperkeratosis around papules or burrows created by the ► [mites](#), often on the hands, feet, genitalia, or axilla. Adults

Scabies, Fig. 1 Typical skin aspects of the initial disease at penis

create burrows in the keratinaceous layer where they live and lay eggs, which give rise to larvae, nymphs, and new adults (► [Pathology](#), Fig. 30b). Metabolic products of the mites give rise to inflammation with lymphocytes and eosinophils in the dermis. In the absence of a thickened stratum corneum, mites elicit more inflammation, more itching, and often ulcers from scratching, sometimes with secondary bacterial infection. Glomerulonephritis may result from secondary streptococcal infection of the lesions.

In immunosuppressed individuals there may be confluent infection with thousands of mites and widespread epidermal scaling, so-called ► [Norwegian scabies](#), that can be diagnosed by scrapings or skin biopsies.

Main clinical symptoms: ► [Pruritus](#), exanthemes, skin scaling.

Scabies, Fig. 2 Typical skin aspects of the initial disease at head

Incubation period: 1–2 weeks.

Prepatent period: First eggs are laid after 15 days.

Patent period: Years, since many generations of females may follow each other.

Diagnosis: Microscopic determination of mites in skin scrapings.

Prophylaxis: Avoid contact with infested people and exchange of clothes; use fresh bed covers etc.

Therapy: Treatment see Acarizides; use of ivermectin or neem-extract (Wash-Away, Alpha-Biocare, Düsseldorf).

Scaphixodes

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus name used as synonym for *Ixodes caledonicus*.

Scatophagidae

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This fly family includes species, which are mid-sized (e.g., *Scatophaga stercoraria*, 5–10 mm in length), covered by brownish or

golden appearing hair and depone their eggs often at human feces. Therefore they become often vectors of human agents of diseases. They occur in the regions of the Palaearctic. Similar species are *Chaetosa punctipes* (Europe, North Asia, Eastern North America), *Norellia nervosa* (Central Europe), *Cordilura puberba* (Westeurope until Sibiria), and *C. albipes* (Europe).

Scerotization

This is the conversion of soft proteinaceous materials to harder and resistant layers in oocysts of ► *coccidia*, in worm eggs, cocoons, or in other cystlike structures that have contact with the environment. Two main processes may lead to sclerotization: ► *quinone-tanning* and dityrosine cross-linking. Quinone tanning occurs, e.g., in egg capsules, eggshells of trematodes, insect cuticle, while protein-dityrosine cross-links are found in yeast cell wall, insect resilin, and coccidian oocysts.

Schaudinn, Fritz (1871–1906)

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Fritz Richard Schaudinn was a German zoologist, who contributed several well-known and important insights in the world of free-living and parasitic protozoans, as well as on bacteria. Together with the medical practitioner Erich Hoffmann he discovered the agents of syphilis (*Treponema* = syn. *Spirochaeta pallida*) in the year 1905, which were mentioned before the publication of John Siegel for a flagellate which he named *Cytohcytes lues*. Just before his early death due to a laboratory infection he detected that the amoeba *Entamoeba histolytica* was the agent of the amoebic diarrhea. His observations on the

Schaudinn, Fritz (1871–1906), Fig. 1 Photograph taken only months before his early death

life cycle of *Plasmodium* species (done in 1901 in Rovinj, Croatia, on demand of the Berlin Health Authorities) confirmed the results of ► *Ross* and Grassi. In April 1906, he got a position at the Hamburg Tropical Institute, but his death already at the end of June 1906 stopped his enormous scientific research work. He founded in the year 1902 the journal “Archiv für Protistenkunde,” which is still today on the market being now named “Protist” promoted by the Publisher Elsevier B.V. Schaudinn’s goal was to unite all research results on single cells in this journal (Fig. 1).

Schellackia

Genus of blood ► *Coccidia* of reptiles. The sporozoites parasitize in erythrocytes, the schizogony occurs in the intestine of the same host. Vectors are culicid mosquitoes and bloodsucking mites – the transmission occurs mechanically as soon as the final host ingests the arthropod containing infected blood.

Schelorbates

Genus of oribatid mites.

Schistocephalus solidus (syn. *S. gasterostei*)

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *schisis* = division; *schizein* = divide; *kephale* = head. Latin: *solidus* = solid.

Geographic Distributions/Epidemiology

In Northern hemisphere, since this parasite is bound to the occurrence of its intermediate fish host = stickleback (*Gasterosteus aculeatus*), which originally was a salt water fish, but became adapted to fresh water during the Pleistocene glacier period. This tapeworm is common in a broad spectrum of final hosts (coastbirds).

***Schistocephalus solidus* (syn. *S. gasterostei*), Fig. 1** Diagrammatic representation of a plerocercoid of *S. solidus*, which reached the same size as its fish host

Morphology/Life Cycle

The adult tapeworms, which belong to the group of Pseudophyllidea and the family Diphyllbothriidae, parasitize the intestine of a broad range of birds, which feed fish. The final host excretes eggs containing the developing larva of the worm (= coracidium), which hatches from the egg and swims around with the help of their cilia. If these coracidia are ingested by the first intermediate host (Cyclopoid copepods), they develop therein into the proceroid stage. If this first intermediate host is ingested by the second intermediate host (stickleback), the infectious proceroid larva passes through the intestinal wall and settles in the body cavity of this fish, where it grows up rapidly to a 6–8 cm long plerocercoid larva. The life cycle is finished when a waterbird ingests this fish. The plerocercoid grows up to an adult pseudophyllid worm (with two longitudinally running sucking grooves) reaching a length of up to 20 cm (Fig. 1).

Schistosoma Granuloma

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Eggs of *Schistosoma mansoni* and *S. japonicum* introduce differently composed granuloma (e.g., in liver), although their adults live in the same blood vessel system (around the intestine of their hosts). In the center of the granulomas of both species one or several eggs are situated. In *S. mansoni* these eggs are surrounded mainly by eosinophilic granulocytes, while in the case of *S. japonicum* neutrophils enclose the centrally located eggs. Then follow (in both cases) collagen fibers from the inner to the outer side layers of macrophages of hepatic stellate cells and a final surrounding layer composed of a mixture of macrophages, neutrophils, and B- and T-cells (Fig. 1).

Schistosoma Granuloma, Fig. 1 Light micrograph of a section through an egg granuloma of *S. mansoni* in the liver of a patient. Note the blue stained collagen

Synonyms

Blood flukes

Classification

Eukaryota, *Opisthokonta*, *Metazoa*, *Eumetazoa*, *Bilateria*, *Platyhelminthes*, *Trematoda*, *Digenea*, *Strigeidida*, *Schistosomatoidea*, *Schistosomatidae*, and *Schistosoma*

History

The earliest recorded account of schistosomiasis japonica is that of Fujii (1847) who described the disease in the Katayama district of Japan (Tanaka and Tsuji 1997). Later Baelz (1883), a sometime professor in the Imperial University at Tokyo, who described the endemic area of Okayama, pictured the conditions under which the people lived in this region and presented his information on certain villages which he had surveyed in the endemic area. The first actual relation of the causative agent, the Oriental blood fluke, to the infection was secured by Katsurada (1904) [1], although Yamagiwa (1890) [1], Kurimoto (1893), Fujinami (1904), and others had previously found eggs of an unknown parasite in various organs (particularly the liver) of individuals who had died in infected areas and believed them to play the etiological role in the disease. Kasai (1903) first found the eggs in the feces. Fujinami (1907) obtained a single female worm in the portal vein of the liver of man in May 1904, which he believed to be the first specimen found (Fujinami 1907). Researchers in other countries in the Far East soon found the worm and recognized the production of the disease in their respective countries. Following the discovery of Katsurada in 1904, Catto (1905) reported the disease in a Chinese at Singaporean who was known to have come from Fujian province of China (Catto 1905). It was likewise recognized soon after this in China (Logan 1905) and in the Philippines (Wooley 1906).

General Information

Human schistosomes include *Schistosoma guineensis*, *Schistosoma intercalatum*, *Schistosoma haematobium*, *Schistosoma japonicum*, *Schistosoma malayensis*, *Schistosoma mansoni*, and *Schistosoma mekongi*. Human schistosomes cause a group of chronic infections called schistosomiasis known also as bilharziasis. According to WHO, schistosomiasis is the second most socioeconomically devastating parasitic

disease (malaria the first) and schistosome is among the top ten most important agents causing more deaths than anything else apart from HIV/AIDS and tuberculosis. It is prevalent in about 76 countries with over 200 million infected and 779 million people at the risk of being infected with schistosoma (Steinmann et al. 2006). *Schistosoma japonicum* (*S. japonicum*) is one of the disease-causing species which is endemic in the Western Pacific such as China, Japan, the Philippines, and Indonesia. In Japan, the disease was controlled in 1978 and declared to be eliminated in 1996. In mainland of China, *S. japonicum* was endemic in 12 provinces. Currently, the transmission of *S. japonicum* is mainly concentrated in five provinces along the middle and lower reaches of the Yangtze River and some mountainous regions of the Yunnan and Sichuan provinces, and over 0.7 million people are thought to be infected with the parasite. Therefore, this disease still remains a major public health concern in China. *Schistosoma japonicum* infection is known to be an important zoonosis. Symptoms correlate with the developmental stages of *S. japonicum*. Human get infected by cercariae penetrating the skin which leads to an allergic dermatitis performing pruritic popular rash at the site of entry. Cardiopulmonary schistosomiasis is associated with larval pneumonitis causing cough, mild wheezing, low-grade fever, and eosinophilia. In addition, *S. japonicum* eggs that pass through the portal drainage via the collaterals into the general circulation can make an occlusion in the pulmonary arteriole leading to thrombi, granulomas, and arteritis. Adult worms rarely are pathogenic, and time between penetration by cercariae and the first appearance of eggs in feces which is termed prepatent period may be ~35 days for *S. japonicum*. Katayama fever is a systemic hypersensitivity reaction and can suddenly starts following the prepatent period which may be due to immune response against eggs and forming immune complexes with a symptom of high fever, lethargy, malaise, myalgia, nonproductive cough, eosinophilia, and patchy infiltrates on chest radiography. In China, Katayama fever not only occurs in people accidentally exposed to transmission but also in people living in endemic

areas and with a history of previous infection. *S. japonicum* has a disposition to reach and grow in the cerebrospinal venules, thus forming the central nervous system granulomas. The symptom may appear as focal epileptic convulsions and transverse myelitis. The main lesions result from eggs trapped in tissues. Eggs are typically found in the liver or in the wall of gut. In the liver, early reaction to oviposition in the presinusoidal periportal space of liver results in inflammatory hepatic schistosomiasis, a granuloma, or both. Later the inflammatory focal may be necrotic and the granuloma site can be replaced by collagen deposition, leading to pathognomonic periportal or Symmer's pipestem fibrosis. This fibrosis leads to portal vein occlusion, portal hypertension, splenomegaly (Fig. 5) collateral venous circulation, portocaval shunting, and gastrointestinal varices, but the lobular architecture of the liver and the liver function are largely unaffected. The most serious, fatal complication of fibrotic hepatic schistosomiasis is bleeding from gastroesophageal varices, which can lead to anemia, hypoalbuminemia, cachexia, and growth retardation. Ascites can be caused by a combination of hypoalbuminemia and portal hypertension (Gryseels et al. 2006).

Main Clinical Symptoms

Dermatitis due to penetrating cercariae, later intermittent fevers (Katayama syndrome), abdominal pain, swellings of liver and spleen, blood in stool, eosinophilia, liver dysfunctions, liver fibrosis.

Incubation period: 1–3 weeks.

Prepatent period: 4–5 weeks.

Patent period: 5–25 years.

Diagnosis: Microscopic determination of eggs in fecal sample.

Prophylaxis: Avoid entering lakes and rivers in endemic regions.

Therapy: Treatment with praziquantel; see Trematocidal Drugs.

Geographic Distribution

See Figs. 1, 2, and 3.

Host specificity has important implication for the geographic distribution of parasites. The geographic distribution of *Schistosoma japonicum* is in Eastern and SE Asia.

Morphology

See Figs. 4 and 5.

S. japonicum worms are yellow or yellow brown and have a body surface of syncytial tegument, a basic bilateral symmetry, oral and ventral suckers, and a blind-ending digestive system including the mouth, esophagus, and bifurcated ceca. A loose network of mesoderm cells is located between the tegument and alimentary canal. The males measure ~1.2 cm by 0.5 mm, while females ~2 cm by 0.4 mm. The eggs are about 55~90 µm by 40~60 µm with a minute lateral spine or knob.

Life Cycle

See Fig. 6.

The adult couples of monogamous male and female with the male bearing the female in his canalis gynecophorus migrate to intestinal venules where the females lay thousands of eggs per day. Some eggs then migrate through the wall of the blood vessels and the intestine; during this process, a ciliated miracidium is coming into being inside the ovum. The eggs are excreted in the feces. On contact with fresh water, the egg-shell bursts and the miracidium is set free. It searches the intermediate host (genera *Oncomelania*) guided by light and chemical stimuli. After entering the snail, it becomes an unciliated miracidium called mother sporocyst; the mother sporocyst then asexually gives rise to multicellular daughter sporocysts later to bifurcated photoprotic cercarial larvae. The snails release cercariae provoked by appropriate

***Schistosoma japonicum*, Fig. 1** The distribution of epidemic situation in China, 2011 (Screenshot, cited from Zhou Xiaonong 2012)

***Schistosoma japonicum*, Fig. 2** Lake-type epidemic spots

temperature and light mainly during daytime. The cercariae spin around the water and find a convenient final host. After penetrating the skin, they become schistosomulae and migrate in the blood

via the lung to the liver and finally to the portal vein or mesenteric vein where they mature as permanently embraced couples and mate, and produce eggs to start another life cycle.

***Schistosoma japonicum*, Fig. 3** Cattles and water buffaloes as one of the most important reservoir hosts

***Schistosoma japonicum*, Fig. 4** Adult worms of *Schistosoma japonicum*

***Schistosoma japonicum*, Fig. 5** Egg of *Schistosoma japonicum*

Treatment

Praziquantel (PZQ, Biltricide): Praziquantel (a pyrazinoisoquinoline) discovered in 1972 is now the most important drug used to control schistosomiasis; the only readily commercially

available drug is originally marketed by Bayer and now is formulated into 600 mg tablets by about 20 countries from technical materials produced in South Korea and China. With its safety and effectiveness and little resistance, the WHO has generated a strategy to guarantee

***Schistosoma japonicum*, Fig. 6** Life cycle of *Schistosoma japonicum*. The adult worms settling in mesenteric veins lay eggs, and eggs migrate into lumen and are discharged in feces. Eggshell bursts and miracidium is set free in fresh water. It searches the intermediate host *Oncomelania* snail and enters it. In the snail body, after

an asexual reproduction of mother sporocysts giving birth to daughter sporocysts then to cercariae. Cercariae are released by snail, penetrate the skin of human, and migrate through blood via lung to liver and to their residential destination

that adults and children infected or at risk of developing morbidity can receive PZQ treatment. PZQ has been used extensively and successfully in national control programs in China, the Philippines, Egypt, and Brazil and has expanded to several countries in Africa for more control of schistosomiasis.

Resistance: Expect for the not significant response to PZQ of several individuals in Egypt in 1992 and a certain tolerance to PZQ treatment of patients with heavy egg burden and at regular dose in Senegal, no other PZQ-resistant isolates has been identified up to date.

Mode of action: energy – metabolism – disturbing drugs. It has high efficacy against adult worms while low efficacy against larvae.

Alternative drugs: Application of PZQ derivatives is hampered due to the lack knowledge of mechanism of PZQ's action in vivo. Malariacidal artemisinin derivatives (e.g., artemether, a methoxy derivative of artemisinin or sesquiterpene), the already used antimalarial, can kill larval stage of *S. japonicum* confirmed by early studies in golden hamsters and have a protective effect against infection with juvenile stage of *S. japonicum* corroborated by clinical trials in China, Africa, and elsewhere. A combination of PZQ and artemether is under evaluation in China, Egypt, the Philippines, and other countries.

Schistosoma Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name and Biology

Greek: *schizein* = divide; *soma* = body. The name refers to the fact that this genus, which formerly had been described as *Bilharzia* has two sexes in contrast to other ► **Digenea**.

This genus of the digenetic trematodes within the worm phylum Platyhelminthes (= flat worm) contains several species, which produce in

Schistosoma Species, Fig. 1 Light micrograph of a typical egg of *S. haematobium*, which is characterized by a strong terminal thorn. When excreted in the urine, it already contains a miracidium larva

contrast to the other hermaphroditic trematodes male and female individuals. The development of a single schistosomal worm includes several stages (adult worm, egg, miracidium, sporocysts, cercaria, schistosomulum), which parasitizes final hosts (humans, vertebrates) and intermediate hosts (water snails).

All *Schistosoma* species are not host specific, and thus some common and relevant species were presented here in two groups: (1) those which are important for **humans** and (2) those which are important for **animals** living close to humans. Their general life cycle is shown in Fig. 1.

Schistosoma Species of Humans

Schistosomes are not host specific, but infect humans and animals. Thus in this chapter those species are summarized, which are important for humans, and in chapter 2 (► *Schistosoma* species of animals) those species are considered, which are important for animals farmed by humans or which live close together with humans.

The following species are of medical importance to humans (Table 1).

Schistosoma haematobium parasitizing the urogenital system

Name

Greek: *schizein* = splitting; *soma* = body; *haima* = blood; *bios* = life. English: bladder worm.

Geographic Distribution/Epidemiology

Large regions in Africa with sufficient water in rivers: Northwest, Northeast, Nile region, South Africa, regions in East and West Africa, West of Madagascar, Arabian half island, Iraq, and some regions in India.

Morphology/Life Cycle

S. haematobium is not host specific but infects many animals besides humans (e.g., rats, goats, etc.). Adult worms exist in contrast to other trematodes, which are hermaphrodites, as males and females. However, *S. haematobium* worms always occur as couples. Flattened males keep females lifelong tightly surrounded within a furrow formed along their ventral side being called *canalis gynaecophorus*. Both sexes of these worms are able to stretch themselves considerably, but they measure 1.5 cm (♂) and 2.5 cm (♀), respectively. These couples live within the veins of the urogenital system of humans ingesting blood so that the intestines always appear blackish through their translucent body. The females give daily birth to 300 eggs, which are characterized by a terminal thorn (Fig. 1) and measure 110–170 × 40–70 µm. When excreted, the eggs only contain a few cells; however, during their wandering phase through the tissues of the

Schistosoma Species, Table 1 Morphological criteria of *Schistosoma* species of humans

Characteristics	<i>S. mansoni</i>	<i>S. japonicum</i> ^a	<i>S. intercalatum</i>	<i>S. haematobium</i>
Male, outer surface	Large tubercles (bosses)	No tubercles	Tubercles with central hook-free places	Small tubercles with many hooks
Female, ovary	Anterior half of body	Posterior half of body	Past mid of body	Midbody region
Eggs in uterus	1–10 (mostly one)	50–300	10–20	20–100
Egg shape	With large lateral thorn	With tiny lateral thorn	With terminal thorn	With terminal thorn
Egg size (μm)	115–180 × 45–70	70–100 × 55–65	140–230 × 50–80	110–170 × 40–70
Site of parasitizing	Veins of the intestine	Veins of the intestine	Veins of the intestine	Veins of the urogenital system
Intermediate hosts/snails	<i>Biomphalaria</i> species	<i>Oncomelania</i> species	<i>Bulinus</i> species	<i>Bulinus</i> species
Reservoir hosts	Rats, mice, monkeys	Mice, dogs, cats, pigs, cattle	Goats, sheep, rodents	Monkeys, hamsters

^aThe ovoid eggs of *S. mekongi* have no thorn and measure only 50–60 × 30–50 μm thus being considerably smaller than those of *S. japonicum*. In Thailand and Malaysia, *S. malayensis* has been described as own species, which has a similar life cycle like *S. japonicum*. *Truncula* snail species are intermediate hosts for *S. mekongi*, and *Robertsiella* species are intermediate hosts for *S. malayensis*. The schistosomes of humans occur in the following venal blood systems:

(a) Urogenital system

See section “*Schistosoma haematobium*”

(b) Intestinal system

Schistosoma Species, Fig. 2 Scanning electron micrograph of a typical miracidium with all cilia (a) and at a stage (b) where some had been removed to show the cell borders of the surface cells (Koie, Copenhagen)

bladder into its lumen, they develop the ciliated ► **miracidium** larva (Fig. 2), which is able to penetrate into water snails after it has hatched in freshwater after being spread within the urine of the host. Inside the snail’s body, finally infectious bifurcated cercariae (Fig. 3) are formed within so-called sporocysts, which after release into water are able to swim around (tail forward) and to finally penetrate into the skin of their new host. During penetration, the bifurcated tail is skipped off, and the anterior portion (**schistosomulum**) stays there. Until after some days, it starts its

wandering to the *vena portae*, where a sexual partner is acquired and a common wandering to veins of the urogenital system is started. Inside these blood vessels, the males stabilize the positions of the couples by the help of their large oral and ventral suckers and by hook-bearing protrusions (bosses) of their tegument.

Symptoms of Disease (Bladder or Urogenital Schistosomiasis)

The severity of the disease depends on the amount of couples that occur for many years inside the

Schistosoma Species,**Fig. 3** Scanning electron micrograph of a typical *Schistosoma* cercaria

infected venal system. However, the following symptoms can be observed:

- (a) Itching (pruritus) at the penetration site of the cercariae. In case of repeated penetration of such cercariae, a so-called ► **cercarial dermatitis** may develop (appears as considerable reddening of the skin and formation of pustules at the penetration site).
- (b) In case of first infection, the hosts develop 4–7 weeks after infection with unspecific fever as a primary symptom.
- (c) About 2–3 months after infection (rarely also only after 2 years), eggs and hematuria occur in the urine. The patients then claim a burning feeling inside the urethra and the need of often urine release.
- (d) In cases of chronic phases of the disease, hematuria and other symptoms may disappear or are reduced.
- (e) The wall of the bladder is sprinkled with 1–2-mm-sized whitish granulomas, when inspecting the bladder by the help of microscopic methods (Fig. 4).
- (f) In cases of huge infections with *S. haematobium*, the following severe symptoms (complications) may occur:
 - **Secondary bacterial infections** of the bladder due to repeated reduced evacuation of the bladder since the contractility of the bladder wall is disturbed due to the numerous egg granuloma and calcifications.
 - **Formation of carcinoma** (common in Egyptian patients) due to constant inflammations of the bladder wall.
 - **Swelling of the genital organs** (e.g., elephantiasis, chronic edemas).

Schistosoma Species, Fig. 4 Macrophoto of the bladder wall of an infected human showing whitish egg granuloma of *S. haematobium* and blood which derives from destroyed tissues after release of the eggs into the lumen of the bladder

Diagnosis

A very good diagnostic symptom for an infection with *S. haematobium* is the occurrence of blood inside the last third of the excreted urine. The typical eggs (Fig. 1) can be easily filtered from urine. Egg excretion reaches highest amounts between 10 a.m. and 2 p.m. If the urine is not microscopically inspected immediately after sedimentation or filtration, 1 ml of 37 % formalin should be added to conserve the material. When egg excretion is not high, small amounts might disappear. Therefore it is recommended to repeat search for eggs. In cases of blood-containing urine, but no observed eggs, immunodiagnostic methods such as ELISA or PCR are needed to diagnose an infection. In cases, when

schistosomal eggs had drifted to other organs (lungs, brain) or in cases of unclear fibrosis in organs, the methods of radiology, sonography, or computer tomography will show the rather large granulomas which are formed around *Schistosoma* eggs in different organs.

Infection

Infectious cercariae of schistosomes penetrate into the skin of patients, who had contact with contaminated freshwater (e.g., rivers, lakes).

Prophylaxis

Do not enter freshwater biotope which potentially harbors cercariae of schistosomes or protect hands (by gloves) and legs (by boots) in cases of works with water contact. **Attention:** Also water drops spread on skin may contain cercariae, since they swim phototactically attracted at the surface of water ponds.

Incubation Period

Four to Seven weeks. Hematuria mostly occurs during the first 8–10 weeks after infection of numerous cercariae.

Prepatent Period

Nine to ten weeks or later.

Patency

Up to 25 years.

Therapy

Drug of choice (WHO recommendation) is a single dose of praziquantel (40 mg/kg bodyweight). Metrifonate was shown to be effective, too, if administered three times 7.5 mg/kg bodyweight at intervals of 7 days.

***Schistosoma mansoni* and Other Species Parasitizing the Human Intestinal System**

Name

Greek: *schizein* = split; *soma* = body; *mansoni* = honors Sir Patrick Manson (1844–1922), while *Schistosoma* species (formerly named *Distomum* and *Bilharzia*) had been first detected in Egypt by the German

physician Theodor Bilharz (1825–1862). The English trivial name for this group is “blood flukes.”

Geographic Distribution/Epidemiology

More than 200 million humans worldwide are infected in tropical and subtropical regions; more than 600 million are at risk especially in regions with poor hygienic conditions.

Morphology/Life Cycle

The different *Schistosoma* species, which live inside the mesenteric veins of the human intestine, are described with their main features in Table 1. The life cycle (Figs. 5, 6) has in principle the same phases as that of *S. haematobium* except for the fact that the couples parasitize inside the mesenteric veins of the intestine. A couple of *S. mansoni* is shown in Figs. 7 and 8, and its typical egg is in Fig. 9. In Fig. 10, a transmission electron micrograph shows a section of the surface of a male worm which is protected by a (here) black-appearing surface coat against attacks of the host's defense system. Figure 11 presents a section through a typical granuloma which occurs as well in liver as in the intestinal wall. A granuloma consists of the centrally situated egg, which is surrounded by daily enlarging layers of eosinophilic granulocytes and collagens. They may reach diameters of up to 2 cm in the liver and thus disturb considerably the functions of the liver. Such granulomas are degenerated within 4–6 months; however, they were replaced daily by new ones, since the adult females produce daily a considerable number of eggs, e.g., females of *S. mansoni* excrete about 300 eggs per day and females of *S. japonicum* even 3,000.

Symptoms of Disease (Intestinal Bilharziasis, Schistosomiasis)

- (a) **Cercarial dermatitis:** At the sites, where the cercariae had penetrated, the skin itching occurs followed by inflammations as signs of a typical dermatitis, which is reduced within some days.
- (b) **Initial relapsing fever** (called ► **Katayama syndrome** in infections with *S. japonicum* and *S. mekongi*), which start after an

Schistosoma Species, Fig. 5 Life cycle of *Schistosoma mansoni*. 1 The adult couples (males bear females in their ► *canalis gynaecophorus*), reach a size of about 1–2 cm and live in the mesenteric veins of the intestine. 2 The typical eggs with a lateral thorn are laid uncleaved by the females within the veins. Some are transported to the liver and block its small venules, thus introducing the formation of up to 10-mm-sized malign liver granulomas. Other eggs migrate through the walls of blood vessels and the intestine guided by help of ► *proteinases* that pass the eggshell. On the way, a ciliated larva (► *miracidium*) is formed inside the egg. 3 Reaching water, the eggshell bursts, and the miracidium is set free and starts swimming. 4–6 Having had contact with an intermediate host (B, i.e., water snails of the genera *Planorbis* or *Biomphalaria*), the miracidium enters the skin while leaving behind its ► *cilia*. The now

unciliated miracidium is called mother ► *sporocyst* (4), which takes its way to the hepatopancreas of the snail. There, the mother sporocyst gives rise to several daughter sporocysts (5), which are finally produced inside many bifurcated phototropic ► *cercariae* (6). These stages leave the snail via the respiratory spiracle and swim around (tail forward) for up to one day until touching a convenient final host (man, rodents). 7 Within 2 min after attachment, the head to the cercaria penetrates the skin and remains there as ► *schistosomulum* for about 3–4 days. Later, it enters the veins of the host and is finally transported to the *vena portae* where the small 1-mm-sized worms join to become couples, grow up reaching maturity in about 5–7 weeks, and start egg production (prepatent period). H head of cercaria (i.e., young worm); T tail of cercaria; TH thorn of eggshell

Schistosoma Species, Fig. 6 Life cycle of *Schistosoma mansoni* and typical eggs and intermediate hosts of *S. haematobium* and *S. japonicum* (According to Piekarski 1987). **A** Final host: man; site of the worms: mesenteric vessels. **1a** Sexually mature pair of flukes of *S. mansoni* (Sambon, 1907). **b** Mature egg of *S. mansoni* (lateral spine). **2** Miracidium. **B** Intermediate hosts: aquatic snails (Planorbidae, e.g., *Planorbis boissyi*, *Australorbis glabratus*). **3a** Sporocyst of the first order (mother

sporocyst); **b** sporocyst of the second order (daughter sporocyst). **4** Free cercaria ("forked-tail cercaria"). **I** *S. haematobium* (Bilharz 1852): egg with miracidium (terminal spine); shells of the intermediate hosts of the species **(a)** *Bulinus truncatus* (North Africa) and **(b)** *Bulinus globosus* (West Africa). **II** *S. japonicum* (Katsurada 1904): egg with miracidium (very small lateral spine); shells of intermediate hosts of the genera **(a)** *Schistosomomorpha*, **(b)** *Oncomelania*, and **(c)** *Katayama*

Schistosoma Species, Fig. 7 Light micrograph of a couple of *S. mansoni*. Note that the intestines are filled with blackish-appearing blood

Schistosoma Species, Fig. 9 Light micrograph of an egg of *S. mansoni* containing already a miracidium larva

Schistosoma Species, Fig. 8 Scanning electron micrograph of a couple of *S. mansoni*

incubation period of about 4–7 weeks. Further symptoms are swellings of liver and spleen, abdominal pain, and disturbances of the intestinal function.

- (c) **Bloody stools:** Depending on the amounts of adult couples in the mesenteric veins, the

amounts of blood in the stools may become visible (bloody-black components) or remain occult. These symptoms start in infections with *S. japonicum* between days 30–44 and in the case of *S. mansoni* mostly 42 days after infection. In *S. intercalatum* infections, it takes longer (50–56 days) until eggs and bloody components appear in the stool.

- (d) **Chronic symptoms:** About 3–6 months after the initial infection symptoms occur, which characterize the chronic course of the disease. The intensity of the symptoms, however, always depends on the number of worms present inside the patient.

– **Intestinal damages and malfunctions:** Diarrheas and phases of obstipations may alternate, and remnants of blood and slime may cover the stool. Inflammations

Schistosoma Species,

Fig. 10 TEM section through the tegument of a male *S. mansoni* worm showing deep invagination, a spine, and the black-appearing ► [surface coat](#) covering also the surface of the invaginations

Schistosoma Species, Fig. 11 HE-stained section through a granuloma around an egg of *S. mansoni* in the liver of a host

especially in the region of the wall of the colon and formation of so-called polyps may be common as a result of the penetration of worm eggs.

- **Liver granulomas and liver swellings:** The formation of numerous up to 1-cm-large granulomas in the liver (Fig. 11) leads to malfunctions of the liver due to pipestem fibrosis (according to Symmers) which may be followed after years by liver cirrhosis with other symptoms such as portal hypertension, ascites, splenomegaly, leucopenia, varicella of the esophagus, etc.
- **Lung symptoms:** In the case of eggs inside lung blood vessels, bronchitis, embolic symptoms, and pulmonary hypertension (cor pulmonale) may occur.
- **Brain:** In very high-grade infection, the brain may be infected by eggs drifted around within the bloodstream. Symptoms are neuromotoric dysfunctions, paresis, cramps, diffuse encephalitis, or meningitis.

Diagnosis

The most important method is the microscopical demonstration of *Schistosoma* eggs (Fig. 9) isolated from stool. Relevant methods are concentration methods such as sedimentation, ► [MIFC](#), SAFC, or thick smears according to Kato-Katz.

Infection

Infection of humans occurs by penetration of cercariae when the person has contact with contaminated freshwater. **Attention:** Cercariae may also be included in droplets of splashing water!

Prophylaxis

Avoid contact with contaminated freshwater; use gloves and boots when working in potentially contaminated waters.

Incubation Period

- (a) Early symptoms just after penetration of cercariae: 6 h – 2 days.
- (b) First reactions, on preadults and adults:

<i>S. mansoni</i>	2–3 weeks
<i>S. japonicum</i>	1–3 weeks
<i>S. intercalatum</i>	4–7 weeks

Prepatent Period

The prepatent period is defined here by the first occurrence of eggs in the feces:

<i>S. mansoni</i>	4–7 weeks
<i>S. japonicum</i>	4–5 weeks
<i>S. intercalatum</i>	6–8 weeks

Patency

Five to twenty five years.

Therapy

Drug of choice for infections due to all species of schistosomes is praziquantel in all stages of the schistosomiasis (3 × 20 mg/kg bodyweight) on a single day. Oxamniquine (1 × 15 mg/kg bodyweight) is only effective against *S. mansoni* (especially against West African strains). In the cases of severe phases of the ► [Katayama syndrome](#) and in the cases of cerebral schistosomiasis (mostly in *S. japonicum*), it is a must to add corticosteroids to the medicaments for treatment. In the cases of portal hypertension together with varices of the esophagus, endoscopic

removal of granulomas is necessary in order to avoid severe bleedings.

Schistosoma Species of Animals

Name

Greek: *schizein* = splitting; *soma* = body. Latin: *bos* = cattle; *japonicus* = from Japan; *indicus* = Indian; *polonicus* = from Poland; *spindalis* = spindle-like; *nasalis* = belonging to the nose; *orientobilharzia* = worm from the East. Greek: *heteros* = different; *trichos* = fine, hairlike. Family names of discoverers: Bilharz, Curasson.

Geographic Distribution/Epidemiology

See Table 2.

Morphology/Life Cycle

See Fig. 6 in *Schistosoma mansoni*. Except for *Trichobilharzia regenti* and *Schistosoma nasale*, which live in the nose veins of their hosts, all other species occur inside liver and mesenterial veins of the intestine, and the eggs are excreted within the feces of the hosts (Figs. 12, 13, and 14).

Symptoms of Disease (Schistosomiasis)

Depending on the species, the symptoms are different. The species in nose veins cause bleeding. Loss of weight, liver and spleen swellings due to granuloma (Figs. 15, 16), rough fur, weakness, bloody/slimy feces, and death in severe cases with a large number of worms are caused by other species.

Diagnosis

Microscopical demonstration of the species-specific eggs (Figs. 12, 13, and 14) in the nasal bleedings or in feces after the use of concentration methods. In case of low-grade infections with low numbers of excreted eggs, serological tests like ELISA or IFAT give reliable results.

Schistosoma Species, Table 2 *Schistosoma* species of animals

Species/size	Final host	Intermediate hosts (genus)	Geographic distribution
<i>S. bovis</i> ♀ = 28 mm/♂ = 15 mm Eggs: 180 × 60 µm	Cattle, goats, sheep, camels, pigs, antelopes, rodents, monkeys, humans	<i>Bulinus</i> , <i>Planorbarius</i>	Corsica, Sardinia, Spain, Near East, North, West, and East Africa
<i>S. mattheei</i> ♀ = 15–25 mm/♂ = 14 mm Eggs: 170 × 70 µm	Cattle, sheep, goats, rodents, monkeys, humans	<i>Bulinus</i>	South Africa
<i>S. curassoni</i> ♀ = 18–26 mm/♂ = 14 mm Eggs: 149 × 63 µm	Cattle, sheep	<i>Bulinus</i>	Mauretania, Senegal, Mali, Nigeria
<i>S. indicum</i> ♀ = 8–26 mm/♂ = 14 mm Eggs: 122 × 57 µm	Cattle, buffaloes, sheep, goats	<i>Indoplanorbis</i>	India, Pakistan
<i>S. spindale</i> ♀ = ~16 mm/♂ = 12 mm Eggs: 85 × 25 µm	Cattle, buffaloes, sheep, goats	<i>Indoplanorbis</i> , <i>Lymnaea</i> (syn. <i>Radix</i>)	India, Southeast Asia
<i>S. japonicum</i> ♀ = 26 mm/♂ = 15 mm Eggs: 85 × 25 µm	Buffaloes, cattle, pigs, dogs, rodents, monkeys, humans	<i>Oncomelania</i>	East Africa, China, Japan, Philippines, Sulawesi, Celebes
<i>S. nasale</i> ♀ = 12 mm/♂ = 8 mm Eggs: 350–380 × 50–80 µm	Cattle, sheep, goats	<i>Indoplanorbis</i> , <i>Lymnaea</i> (syn. <i>Radix</i>)	India, Southeast and East Asia
<i>Orientobilharzia turkestanica</i> ♀ = 7 mm/♂ = 5 mm Eggs: 60–70 × 50 µm	Cattle, buffaloes, horses, camels	<i>Lymnaea</i>	Russia, Middle East, East Asia
<i>Heterobilharzia americana</i> ♀ = 9–18 mm/♂ = 10 mm Eggs: 87 × 70 µm	Raccoon, lynx, opossum, dogs, roe deer	<i>Lymnaea</i>	USA
<i>Trichobilharzia</i> species ♀ = 5–7 mm/♂ = 4 mm Eggs: 140 × 210 µm	Ducks	<i>Radix</i> (syn. <i>Lymnaea</i>)	Europe, Asia
<i>Bilharziella polonica</i> ♀ = 2 mm/♂ = 2 mm Eggs: 400 µm	Geese, ducks, water birds	<i>Radix</i> (syn. <i>Lymnaea</i>)	Europe, Asia, Africa, North America

Schistosoma Species,
Fig. 12 Light micrograph of an egg of *S. spindale*

Infection

Percutaneous via penetration of cercariae during contact within contaminated freshwaters.

Prophylaxis

Reduction of snail populations at places where farmed animals drink water.

Schistosoma Species, Fig. 13 Light micrograph of an egg of *S. japonicum*

Incubation Period

There are quick reactions (dermatitis within hours) on penetrating cercariae followed by general symptoms within the next 4–7 weeks and later chronic symptoms due to granuloma formation in liver and intestine, respectively, nose.

Prepatent Period

<i>S. bovis</i>	44 days
<i>S. matthei</i>	42 days
<i>S. japonicum</i>	40 days
<i>S. nasale</i>	77–116 days
<i>S. spindale</i>	46–76 days
<i>S. szidati</i>	~40 days

Patency

Years.

Therapy

Praziquantel is the drug of choice ($3 \times 10\text{--}35$ mg/kg bodyweight) to cure animal schistosomiasis. However, the cost for this cure is rather high, so elimination of possible vector snails on meadow waters is more reasonable.

Schistosoma Species Protein Kinases

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Recently it was shown that protein kinases (PKs) control important biological processes in schistosomes as well as that other PKs are involved in the etiology of cancer. This led to the development of several anticancer drugs that inhibit deregulated PKs. Thus there are approaches to use these PKs-blockers as tentative new antischistosomal medicaments in future, if praziquantel should loose its activity against schistosomes.

Schistosoma: Integument/Surface Coat

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The surface of the blood fluke, *Schistosoma mansoni*, has been analyzed very intensively in

the past few years in order to find antigens for vaccination against this important parasite of man in the tropics (► [Platyhelminthes](#)/► [Integument](#)). As in all ► [digenea](#), all larval stages seem to have a ► [surface coat](#) containing proteoglycans (Fig. 1). In the miracidium even the cilia are covered by a surface coat. Mother sporocysts of *Schistosoma mansoni* (like those of ► [Fasciola hepatica](#)) show an amplification of the surface area by a mixture of branching folds and ► [microvilli](#). They are covered by a fuzzy surface coat. Vesicles at the base of the microvilli suggest the occurrence of ► [endocytosis](#). Rediae also have a surface coat. Although there is evidence that they are able to take up nutrients through the mouth into the small digestive system, absorption of nutrients by endocytosis through the ► [tegument](#) has been observed for glucose, a polysaccharide, and amino acids.

The cercariae of *S. mansoni* have a normal trilaminar outer membrane of the tegument which is covered by a 1 µm-thick fibrillar surface coat. Histochemical investigations have shown that it does not bind cationic colloidal iron at low pH and that it contains at least glycoproteins, glycolipids, and perhaps proteoglycans. After artificial removal of the filamentous surface coat from cercariae, the surface of the tegumentary membrane will bind cationic dyes at low pH. Therefore, it has been assumed that such binding sites are normally masked by proteoglycans or other substances. Discoid bodies are formed by the rough endoplasmic reticulum (rER) and Golgi system and then incorporated into the external membrane system. In this way the membrane is constantly renewed. It has been suggested that it is involved in nutritional, osmoregulatory, and excretory activities, but these functions have still to be substantiated.

The tegumental surface, especially the surface coat, has to protect the cercaria in the snail during the free-swimming phase and during penetration into the final host. This is the most dangerous phase. It was already shown by McLaren that about 60 % of the stages which are in the host are killed in the skin region of vaccinated mice. When cercariae are placed in homologous antiserum, the filaments of the surface coat react with

Schistosoma:
Integument/Surface

Coat, Fig. 1 Transmission electron micrograph of the integument (= tegument) of *Schistosoma mansoni* (gray) showing a longitudinally sectioned spine, deep invaginations, and the blackish appearing surface coat

the antiserum. A conspicuous sheath is formed immediately by this “► Cercarien-Hüllenreaktion.” After penetrating the host's skin the cercaria transforms into the ► schistosomulum. This stage has a thinner surface coat. The loss of surface coat material appears to be concomitant with a dramatic change in permeability during transformation of the cercaria into the schistosomulum. The cercaria is able to live in freshwater, whereas the schistosomulum undergoes ► vesiculation and dies in freshwater. It has been suggested that proteoglycans of the surface coat might act as a permeability barrier which is lost during transformation.

Secretory vesicles, which were called membranous bodies, are formed in the perikarya of the tegument of the schistosomula. They are bound by two membranes. Their contents are either electron lucent or granular or membranous. Carbohydrate-containing material was localized in these vesicles, suggesting that this material is used for the formation of the surface coat. The vesicles tend to fuse with the external tegumentary membrane or with each other, thus forming large vesicles which fuse afterward with the external tegumentary membrane. In this way the original, normal plasma membrane of the cercaria is replaced by a heptalaminate external membrane. Microvilli with a bulbous tip are formed which are pinched off. Thus the original membrane of the cercaria seems to be eliminated. This process ends about 60 min after skin penetration, and the young and

adult schistosomes show two membranes as ► body cover even lining the tubelike foldings of the surface (► Platyhelminthes/► Tegument). Immunological investigations have shown that the cercarial membrane is replaced within 3 h after skin penetration and that the unique heptalaminate membrane with the surface coat of the schistosomula is exchanged during migration through the host. Chase incubations of adult *S. mansoni* *in vitro* with cationized ferritin in Eagles' medium have shown that by 4 h most of the label and the external tegumentary membrane to which it is bound have been lost to the medium. Therefore it has been assumed that under these *in vitro* conditions the surface membrane has a half-life of 2–3 h. However, Ruppel and McLaren used the human complement component C3b to label the surface of adults, 3-week-old juveniles, and 6-day-old lung stages. C3b is known to bind *in vitro* to the surface of all developmental stages of *S. mansoni*. Its presence on the surface of these stages was shown by fluorescent-labeled antibodies against C3b. Labeled schistosomes were cultured *in vitro* for periods of up to 2 weeks. In contrast to the results of Wilson and Barnes, these authors could demonstrate that *in vitro* the turnover of the external tegumentary membrane is minimal, except at the anterior part of the parasite including the suckers. If labeled viable skin schistosomula were injected intravenously into mice and subsequently recovered from the lungs after varying periods, it could be shown that most

of the label was lost in a patchy way, either in only a few minutes or, in most cases, within several hours. This demonstrates clearly that a rapid turnover of surface materials occurs *in vivo*.

Another interesting phenomenon is the change of antigens and their carbohydrate residues during maturation from cercaria to adult worm (Tables 1 and 2). Surface binding of lectins which were either labeled radioactively or with a fluorescent dye revealed the presence of mannose and/or glucose and of N-acetylglucosamine residues and the absence of galactose, N-acetylgalactosamine, and fucose residues in all stages examined (Table 1).

The change of antigenic proteins on the surface of different developmental stages of *S. mansoni* was demonstrated by radioiodination and SDS-PAGE followed by autoradiography and by immunoblotting. Two glycoproteins with apparent molecular weights of 38–32 kDa are the major antigenic material in the surface of the cercaria. It has been suggested that they are associated with the surface coat. These glycoproteins are gradually replaced by a single dominant glycoprotein. It has an apparent molecular weight of 38 kDa and expresses identical epitopes to those of the complex with an apparent molecular weight of 38–32 kDa. This reorganization process seems to occur in conjunction with the appearance of and as part of the new heptalaminate membrane. The reorganization is completed 48 h after infection. Low molecular weight proteins appear on the surface of the schistosomula. The enzyme alkaline phosphatase is expressed on the surface of worms in the liver 3 weeks after infection. It has an apparent molecular weight of 62 kDa and seems to be related to a metabolically very active stage of development. It has been assumed that the polypeptide of 92–98 kDa might be of host origin.

A very interesting phenomenon concerns at least three antigens of 32, 22, and 18 kDa. These are exposed on the surface of younger stages, whereas in adult worms they are present but not

***Schistosoma*: Integument/Surface Coat, Table 2** Change of surface antigens of *Schistosoma mansoni* stages during maturation

exposed at the surface. Their sequestration deeper into the membrane has been related to the high lipid content of the external tegumentary membranes and the ability of adult worms to evade the immune mechanisms of the host; however, they are considered promising targets for vaccines, as is the 28 kD aglutathione S-transferase of *S. mansoni* (Sm 28 GST). Another important finding was that the surface membranes of all schistosomal developmental stages (even eggs) are provided with specific glucose transporter proteins (GTP) recently identified on the basis of cloned cDNAs and designated as SGTP1-SGTP4. The SGTP4 (as integrating part of the ► [cell membrane](#)) transports glucose from the bloodstream through the apical double bilayer membrane, which is formed just after penetration of the cercaria into the skin, into the tegument. Then SGTP1 transports the glucose through the single basal cell membrane of the tegumental layer to other cells (muscle, parenchyma).

Schistosomiasis, Animals

Important Species

- *S. bovis*: in North and East Africa, Iran. The males reach a length of 15 mm, females 28 mm, eggs: 180 × 60 µm with terminal spine, in faeces; intermediate hosts: *Bulinus* and *Planorbis* snails.
- *S. mattheei*: in East, South, Central Africa; males 14 mm, females 25 mm; eggs 170 × 70 µm with terminal spine, found in faeces and urine (10 %).
- *S. nasale*: in India in buffaloes and cattle in the veins of the nose (prevalence up to 50 %); worms: females 11 mm, males 8 mm; eggs: boomerang-shaped, 350–380 × 50–89 µm, are excreted in nasal slime; intermediate hosts: *Indoplanorbis* snails.
- *S. spindale*: in India and Far East; in cattle, buffaloes, small ruminants, and dogs; adults (16 mm) live in mesenteric veins, but also in veins of the whole body; eggs with

2 protrusions (Figs. 1 and 2) reach a size of $300 \times 80 \mu\text{m}$; intermediate hosts: *Indoplanorbis* snails.

- *S. japonicum*: appearance and occurrence as in humans.

Pathology

Different species of the genus ▶ *Schistosoma* give rise to infection in several domestic animals. ▶ *S. japonicum* have been found within the

mesenteric and hepatic portal veins of pigs and dogs. Although ▶ *Schistosoma* infections in ruminants are highly prevalent in certain regions of the tropics and subtropics. The general level of infestation is often too low to cause clinical disease or losses in productivity. Levels sufficiently high to cause outbreaks of clinical schistosomosis do occur occasionally and infestation becomes manifest either as an intestinal syndrome which is usually self-limiting, or as a chronic hepatic syndrome, which is usually progressive. The intestinal syndrome is caused by the deposition of large numbers of eggs in the intestinal wall (Figs. 1 and 2) and usually follows a heavy infestation in a susceptible animal, i.e., an animal in which the capacity of the host to suppress the egg laying of the parasite has not been stimulated by previous infestations. This has been reported among cattle, sheep, and goats infected with either *S. bovis* or by *S. matthei*. As the faecal egg counts rise sharply with the onset of egg production the animal develops a mucoid and then haemorrhagic ▶ *diarrhoea*, accompanied by ▶ *anorexia*, loss of condition, general weakness and dullness, roughness of coat ▶ *hypoalbuminaemia*, and paleness of mucous membranes. Death may occur a month or two after the onset of clinical signs. In most cases, the animal makes a spontaneous but slow recovery. The primary cause of the diarrhoea is the passage of large numbers of eggs through the wall of the intestine. The ▶ *anaemia* is usually due to an increased rate of red cell removal from the circulation; while haemodilution and the inability to mount a sufficiently effective erythropoietic response are of secondary importance. The

Schistosomiasis, Animals, Fig. 1 Egg of *Schistosoma spindale* from the intestinal wall of a buffalo in Thailand

General Information

This complex of diseases is caused by *Schistosoma haematobium*, *S. intercalatum*, *S. japonicum*, *S. mansoni*, and *S. mekongi*. Schistosomiasis is acquired from free-swimming freshwater ► [cercariae](#) that penetrate the skin or are swallowed with fecally contaminated water from snail-infested sources (► [Schistosoma](#)). As they penetrate the skin, cercariae lose their tails and become **schistosomules**. Growing couples of

monogamous male and female migrate to intestinal (*S. mansoni* and *S. japonicum*) or urogenital (*S. haematobium*) venules where females lay hundreds to thousands of eggs per day. The great variety of lesions are superbly described and illustrated by McCulley et al. and Lichtenberg. The granulomatous response is subject to multiple immunologic mechanisms.

Distribution

There are an estimated 200 million people, in 74 countries, infected with schistosomes. Intestinal schistosomiasis caused by *S. mansoni* occurs widely in tropical Africa, in some parts of North Africa, and Southwest Asia as well as parts of South America and the Caribbean (Figs. 1 and 2). *S. intercalatum* is limited to parts of tropical Africa, *S. japonicum* occurs in some countries bordering on the western Pacific, *S. mekongi* is restricted to parts of the central Mekong basin, and *S. haematobium*, the cause of urinary schistosomiasis, is widely distributed in Africa and also found in Southwest Asia. The geographical distribution of the various species follows that of the obligatory snail host in association with suitable environmental temperatures for the parasite's extrinsic development.

Pathology

Acute schistosomiasis occurs in immunologically naive, previously uninfected hosts, e.g., tourists and Peace Corps workers, and is characterized by hyperreactivity to schistosome worm and egg antigens. In contrast, chronic schistosomiasis mainly affects people born and residing in endemic areas. Most individuals chronically infected with schistosomes have few or no symptoms, but 5–10 % develop severe disease. Portal hypertension, as a consequence of liver fibrosis, is the major cause of ► [morbidity](#) and mortality in *S. mansoni* and *S. japonicum* infection, while *S. haematobium* infections often result in mass lesions of the bladder and ureters.

Schistosomiasis, Man, Fig. 1 World map showing the distribution of *S. haematobium* (black) and *S. japonicum*/*S. mekongi* (grey) in Asia

Schistosomiasis, Man, Fig. 2 World map showing the distribution of *S. mansoni*

Dermatitis

Dermatitis starts as a macular, and later papular, rash covering the areas in contact with contaminated water. This persists for 2–3 days if infection is with species which mature in man. However, schistosomules from bird schistosomes may give rise to urticarial eruption with intense itching, vesicles, and, if secondarily infected, pustules. Depolymerization of the interstitial ground substance may be seen surrounding the schistosomules, and protein precipitates may be found at their oral and genital pores. Histologically, a mixed inflammatory exudate is present usually with ► [eosinophilia](#), especially with nonhuman schistosomules, most of which probably die in the skin.

The pathology is complex and will be discussed as a central theme, followed by the variations seen in the several organs involved. The variable picture that can be seen in the same patient is explained in part by the chronic active infection, with a continual arrival of new eggs, so that old and recent inflammation may be side by side and intermixed. Differences between patients are believed to depend on usual multifactorial variables of intensity and duration of infection, nutritional state, various elements of immunity and hypersensitivity, and presence of other infections.

Acute Schistosomiasis

Acute schistosomiasis is acquired from exposure to large doses of cercariae when drinking and swimming in fecally contaminated snail-infested water. It is seen as acute febrile illness 3–4 weeks after exposure, with abdominal symptoms coincident with the onset of ► [oviposition](#). The intestinal mucosa is edematous and hyperemic with small hemorrhages, early granulomas, and shallow ulcers with eosinophils.

Adult schistosome pairs are present in the radicles of the portal vein around the colon or in the pelvic and vesical plexuses around the urinary bladder. The female is usually surrounded by the male in the lumen of a vessel without an apparent lesion or inflammatory reaction (► [Pathology](#)/Fig. 23A). The male attaches to the venous wall and prevents the pair from being swept away by

the bloodstream. To lay eggs, the pair migrates into the wall of the viscus and the female wedges its body into the small veins to deposit its eggs there. The adult worms are long-lived with reports of persistence for 20–50 years after leaving an endemic area.

Eggs

Eggs appear in stools 40–80 days after primary *S. mansoni* infection. Dysentery with blood, mucus, and necrotic tissue may accompany the eggs. Early in the course there is diffuse eosinophilic hepatitis, which is followed by granuloma formation around individual eggs.

Eggs are found typically in the walls of the gut or the bladder and atypically in many other organs to which they have usually been swept by the bloodstream (► [Pathology](#)/Figs. 1, 23). The eggs become surrounded by inflammatory reaction, usually a granuloma, whether the embryo is alive or dead (► [Pathology](#)/Fig. 24). Antigenic material exudes from the eggs, particularly through the spine when present. The inflammatory reaction is quite variable. The eggs may be surrounded by eosinophils, with a mixed eosinophilic and neutrophilic inflammatory reaction peripherally. These inflammatory cells may undergo necrosis (► [Pathology](#)/Figs. 1C, 26). Other eggs may be surrounded by well-developed epithelioid and occasionally giant cells, followed successively by zones of lymphocytes and fibrosis. The granulomas are larger, more focal, and more structured during the early infections when fewer eggs are present. The granulomas during later infection may be largely necrotic or may have undergone fibrosis. Some eggs are surrounded by a layer of eosinophilic fibrinoid material, found also around other chronic antigenic sources, the so-called Splendore-Hoeppli reaction (► [Pathology](#)/Fig. 1B). During ► [chronic infections](#) of long-standing, the inflammation is varied, with lymphocytes, eosinophils, and fibrosis interlaced with various stages of granuloma associated with eggs or egg masses.

Evidence has been presented which shows that together with the spines of *S. mansoni*, *S. mekongi*, and *S. haematobium*, the inflammatory reaction is instrumental in propelling the eggs

toward the lumen of the gut or bladder before the contained ► [miracidium](#) dies. Eggs with dead miracidia gradually lose their inflammatory reaction and their shells often calcify (► [Pathology](#)/Figs. 24A, B).

Intestinal Lesions

Intestinal lesions produced by eggs are either granulomas or diffuse or segmental fibrosis of the submucosa, mainly of the colon. Inflammatory polyps may extend into the lumen, with egg masses forming the nidus. Both fibrosis and polyps may lead to obstruction. *S. japonicum* also gives rise to lesions in the small intestine. Localized masses of eggs trapped in the serosa are sometimes referred to as ► [bilharziomas](#); they may form polypoid projections into the peritoneum. The mesenteric lymph nodes may be enlarged from lymphoid ► [hyperplasia](#) during earlier infection, or they may be small from lymphocytic depletion during late ► [chronic infection](#).

Liver Lesions

Liver lesions are produced by eggs and adult worms carried through the portal vein. The eggs produce small granulomas similar to those in the gut or bladder wall. However, dead adult worms carried to the liver elicit large lesions, with necrosis and around the worm, accompanied either by a mixed granulocytic inflammatory reaction, a **granuloma**, or both (Fig. 3). Much liver tissue is destroyed. This is particularly so after chemotherapy when the worms dislodge and large numbers are swept simultaneously into the liver. Scarring is seen principally in the portal areas and, when pronounced, is called Symmers' pipe stem fibrosis (► [Pathology](#)/Fig. 18G) This term alludes to the gross appearance of a cross section of fixed liver, which looked to Symmers (1904), as if "a number of white clay-pipe stems had been thrust at various angles through the organ." This fibrosis leads to portal hypertension with the eventual formation of dilated venous collaterals, or varices, usually around the lower esophagus, connecting the portal with the general venous circulation. The esophageal varices may bleed when ulcerated. The lobular architecture of the liver is generally preserved and so is liver function, unlike in cirrhosis.

Schistosomiasis, Man, Fig. 3 Liver granulomas around an adult *Schistosoma mansoni* (left) and two eggs (right)

Splenic Enlargement

Splenic enlargement secondary to the liver fibrosis is often found with chronic schistosomiasis. It is usually characterized by venous congestion rather than specific egg-related lesions.

Urogenital Schistosomiasis

Urogenital schistosomiasis is usually due to *S. haematobium* which deposits its eggs in the venous plexuses around the bladder, ureter, seminal vesicles, prostate, fallopian tubes, etc. The bladder often contains focal polypoid mucosal lesions (Fig. 4) or plaques of large masses of eggs (► [Pathology](#)/Fig. 24B) attributed to relatively sessile single pairs of adults. Eggs of *S. haematobium* in the bladder and ureteral wall appear to have a tendency to calcify giving a "sandy" appearance to these focal lesions and making them visible roentgenologically. The microscopic lesions are similar to those described earlier except that diffuse inflammatory reaction and fibrosis are more common than the large granulomas. Ureteral polyps, strictures, and obstruction may lead to pyelonephritis and hydronephrosis. Cystitis with squamous metaplasia and ulceration leading to hematuria are common findings throughout the course of *S. haematobium* infection. Carcinomas of the

bladder (► [Pathology](#)/Fig. 24B), of which half are squamous cell carcinomas, and almost half transitional carcinomas, with a few adenocarcinomas, are late complications.

Main Clinical Symptoms

Unspecific fevers, hematuria, feeling of a burning in the urethra, and possibly later development of carcinomas.

Incubation Period

Four to seven weeks.

Prepatent Period

Nine to ten weeks.

Patent Period

Twenty-five years.

Diagnosis

Microscopic detection of eggs in the urine (Fig. 5).

Prophylaxis

Avoid entering lakes and rivers in endemic regions.

Therapy

Treatment with praziquantel, see ► [Trematodocidal Drugs](#).

Schistosomiasis, Man, Fig. 4 Granulomas in the wall of human bladder due to *Schistosoma haematobium*; note the bloody fluids around protruding eggs

Pulmonary Schistosomiasis

Pulmonary schistosomiasis is produced by *S. haematobium* eggs escaping into the general venous circulation and by *S. mansoni* and *S. japonicum* eggs that pass through the portal drainage via the collaterals into the general circulation. These eggs occlude the pulmonary arterioles giving rise to thrombi, granulomas, and arteritis. With heavy infections there is significant obstruction, with pulmonary hypertension, leading to cor pulmonale dilatation and hypertrophy of the right heart.

Schistosomiasis, Man, Fig. 5 The eggs of the four important *Schistosoma* spp. (from left: *S. mansoni*, *S. japonicum*, *S. intercalatum*, *S. haematobium*)

Central Nervous System Granulomas

Central nervous system granulomas can be produced by any of the schistosome species but especially by *S. japonicum* due to its proclivity to reach and grow in the cerebrospinal venules. Because of the calvarial exoskeleton, the space-consuming lesion within it impacts on the brain. So the cerebral or meningeal granulomas surrounding the eggs of *S. japonicum* (► [Pathology](#)/Fig. 24C) may give rise to focal epileptic convulsions and those of the cord to transverse myelitis. Because of the association of central nervous system involvement with light, aberrant, or early infections, the expected diagnostic findings of eggs in the stool or urine may be absent.

Miscellaneous Lesions

Miscellaneous lesions include ectopic eggs which may be found in many other organs, but because the eggs are usually few in number, the lesions produced tend to create few or no symptoms. Development of dilated anastomoses between portal and systemic veins has been commented upon. They may bleed, usually into the esophagus. ► [Bilharziomas](#) are granulomatous and fibrotic lesions that develop around egg masses away from the mucosa (Figs. 3 and 4). Glomerulonephritis associated with the deposition of immune globulin in glomeruli has been described in patients with *S. mansoni* infection. Chronic *Salmonella* infection is sometimes associated with schistosomiasis, with bacteria growing within the adult schistosomes. This may resemble a systemic infection or pyelonephritis. Pigmentary deposits of hematin are often found in the sinusoidal lining cells of the liver which resemble those formed in ► [malaria](#), or artifactually by acid formalin. The schistosomal pigment is produced by the breakdown of blood ingested by the adult schistosomes.

Schistosomiasis is often associated with malnutrition and other infectious agents, such as hookworm, ► [Ascaris](#) spp., malaria, tuberculosis, amebiasis, and bacillary dysentery, and lesions and symptoms may overlap. Infection with *S. mekongi* is often accompanied by ► [Opisthorchis viverrini](#). Incidentally to the investigation of these other clinical entities,

subclinical schistosomiasis may be diagnosed. Because of the long survival of adult schistosomes and the worldwide travel of the human host, chronic infections may be found away from the areas of endemicity. There are several species of schistosomes parasitic in animals which are also capable of giving rise to light infections in humans.

Intestinal Schistosomiasis in General

Main Clinical Symptoms

Dermatitis due to penetrating cercariae, later intermittent fevers (► [Katayama syndrome](#)), ► [abdominal pain](#), swelling of liver and spleen, blood in stool, eosinophilia, liver dysfunctions, and liver fibrosis.

Incubation Period

S. mansoni: 2–3 weeks, *S. japonicum*: 1–3 weeks, *S. intercalatum*: 4–7 weeks.

Prepatent Period

S. mansoni: 4–7 weeks, *S. japonicum*: 4–5 weeks, *S. intercalatum*: 6–8 weeks.

Patent Period

Five to twenty-five years.

Diagnosis

Microscopic determination of eggs in fecal samples (Fig. 5), ► [Serology](#).

Prophylaxis

Avoid entering lakes and rivers in endemic regions.

Therapy

Treatment with praziquantel, see ► [Trematocidal Drugs](#).

Immune Responses

One of the main histopathological findings in schistosomiasis is the formation of granulomas around schistosome eggs, which is also frequently

found in experimental schistosome infections of mice, monkeys, and other hosts. Although the circumoval granulomas in experimental infections are massive compared to infections in humans, much has been learned about the responsible immunoregulatory processes especially by analyzing granuloma formation in response to *S. mansoni* eggs in mice.

B Cells and Antibodies

A variety of antibodies can be produced against different antigens of adult worms, but protective immunity against reinfection appears to be mainly operative against larval stages. Numerous in vitro studies in experimental and human schistosomiasis have clearly pointed out the essential role played by antibodies in various effector and regulator mechanisms according to their isotypes. However, the course of infection as well as the relative importance of antibodies varies in different experimental hosts. Antibodies of the IgG and IgE isotypes are directly involved in the in vitro killing of schistosome larvae in association with effector cell populations such as eosinophils, macrophages, and platelets. These antibodies also induce protection against a schistosome challenge when transferred to naive rats. In rats and rhesus monkeys, there is a short self-limiting infection after which persistent low worm burden is controlled by concomitant immunity. In rats, the protective immunity involves antibodies of IgE and IgA isotypes. In humans infected with *S. mansoni*, a parallelism of the generation of IgA antibodies against the protective recombinant 28 kDa glutathione S-transferase and acquisition of resistance to reinfection has been observed. Functional analysis revealed that these IgA antibodies not only inhibited the activity of the glutathione S-transferase but also markedly impaired schistosome ► *fecundity*, by suppressing both the egg production by adult female worms and the hatching capacity of schistosome eggs into viable miracidia.

Beside these protective antibodies, several blocking antibody isotypes have been reported. In humans, IgM and IgG₂ antibodies specific for glycanic schistosome antigens prevented the eosinophil-dependent killing by the IgG fraction

of the same sera. Furthermore, in *S. haematobium*-infected children immunity to reinfection correlated with increased levels of IgE and decreased levels of IgG₄ antibodies.

In addition to their role in antibody production, B cells participate in the modulation of granuloma formation as has been demonstrated in *S. mansoni*-infected B cell-deficient (μ MT) mice. Due to mechanisms not defined so far, the B cell-deficient mice displayed an increased hepatic fibrosis and an enhanced Th1-type T cell response.

T Cells

The formation of granulomas surrounding eggs of ► *Schistosoma* is clearly T cell dependent, and immune serum was shown to be not important for the formation or modulation of these lesions. Th2 cytokines are of paramount importance for the granuloma development in experimental infections with *S. japonicum* and *S. mansoni*. Seven to 10 days after injection of eggs or 5–6 weeks after infection with *S. mansoni*, the time when egg laying begins, the cytokine response of mice evolves from a Th0 to a Th2 pattern. While in the lung model using *S. mansoni* eggs, treatment with anti-IL-4 antibodies markedly reduced the size of granulomas in mice, injection of anti-IFN- γ mAb enhanced both the granuloma size and the parasite-specific Th2 response. However, the transfer of Th0, Th1, and Th2 clones or cell lines all augmented granuloma formation in naive recipient mice.

In *S. mansoni*-infected mice, anti-IL-4 treatment had only a moderate to minimal effect on the size of granulomas, but hepatic fibrosis was greatly reduced. Surprisingly, both the granuloma formation as well as the development of hepatic fibrosis was not significantly altered in IL-4-deficient mice when compared to wild-type mice, suggesting compensatory mechanisms in these knockout mice. Another Th2 cytokine, IL-5, appears to be of importance for the development of tissue eosinophilia, but anti-IL-5 treatment did not significantly influence the granuloma size. A central, nonredundant role of IL-2 is demonstrated by the findings that anti-IL-2 treatment or infection of mice depleted of IL-2

receptor expressing cells by injection of an IL-2-fusion toxin both resulted in the reduction of granuloma size and hepatic fibrosis. Since concomitantly there was a reduced Th2 response, IL-2 is most likely essentially involved in the generation of disease-aggravating Th2 cells.

Cytokine treatments of infected mice generally had the effects expected from the anticytokine treatments. While IL-2 and IL-4 administration increased the granuloma sizes, IFN- γ application had the opposite effect and reduced hepatic fibrosis. In line with the latter finding, IL-12 dramatically downregulated the granuloma formation, largely through the stimulation of IFN- γ production from NK cells.

In summary, the formation of egg-induced granulomas in experimentally infected mice may be viewed as Th2-driven process supported by chemotactic factors derived from the eggs. Although the information on the immune response in humans is much more scarce, the immunoregulatory processes might be similar: There were elevated levels of IL-4 in sera of schistosome-infected patients and IL-4 levels after *in vitro* polyclonal stimulation correlated positively with the intensity of schistosome infection, while there was a negative correlation with the amounts of IFN- γ produced. However, enhanced production of IL-4 and IL-5 by cells from Egyptian patients in response to *S. haematobium* adult worm antigens correlated with immunity against reinfection.

One of the key features of schistosomiasis in mice is the immune downregulation of the granulomatous response during chronic infection. In *S. mansoni*-infected mice, the size of newly formed granulomas peaks at 8 weeks postinfection. The subsequent downregulation of granulomas is accompanied by decreased cutaneous reactions to soluble egg antigens (SEA) and a decreased proliferative response and cytokine production of CD4⁺ cells. Several findings are consistent with the idea of active suppression of immune responses. SEA suppresses LPS-induced activation of immature murine dendritic cells, including MHC class II, costimulatory molecule expression, and IL-12 production. SEA-augmented LPS-induced production of IL-10 is in

part responsible for the observed reduction in LPS-induced IL-12 production. Diminution of hepatic granulomas was observed upon transfer of spleen cells from chronically infected (16–24 weeks) mice, and this adoptive suppression required the presence of histocompatible CD8⁺ T cells. Since adult thymectomy results in almost complete lack of the suppressive T cell population, recent thymic emigrants are obviously required for the maintenance of the suppressor cell population. The mechanisms by which CD8⁺ T cells suppress CD4⁺ Th populations are still a matter of debate.

An alternative, not necessarily exclusive, possibility for suppressive activity of CD8⁺ T cells has been proposed involving IFN- γ as key regulatory molecule. In CD8⁺ T cells from *Schistosoma*-infected mice, the frequency of cells expressing the activation phenotype CD44^{high} L-selectin^{low} is increased, and these cells produce IFN- γ in the presence of IL-2 after TCR stimulation. Since some of these CD8⁺ T cells are responsive to schistosome antigens, and CD8⁺ T cells have been found in close proximity with CD4⁺ T cells within granulomas, it is tempting to speculate that the egg-induced lesions could be the site of CD4/CD8 T cell interaction. Recently, it was shown that CD4⁺ CD25⁺ T_{reg} isolated from hepatic granulomas and from lymphoid tissues are a main producer of immunosuppressive IL-10 in schistosome-infected mice, thus contributing to an enhanced Th2 cell response.

In infected humans, a failure to develop immune downregulatory mechanisms has been observed which correlates with clinical disease: Antigen-induced proliferative responses of PBLs *in vitro* were high in the majority of acutely infected patients and amongst ambulatory patients with hepatic or hepatosplenic disease, while asymptomatic chronically infected patients were predominantly low to moderate responders. Interestingly, immune responsiveness is regained after curative chemotherapy, presumably by removing egg antigens which might be of importance for sustained immunoregulatory constraints.

Fibrosis underlies most of the chronic pathology associated with schistosome infections.

While in mice most hepatic fibrosis is associated with granulomas, in humans the relation appears to be less stringent. Type I and III are the predominant collagen isotypes synthesized in both human and murine infections, and a switch from predominant type I to type III collagen synthesis has been reported to occur during the chronic phase of infection. The fibrogenic process is regulated by T cells and macrophages interacting with cells of the mesenchymal/fibroblast lineage. Cytokines are certainly involved in these interactions, since anti-IL-4 treatment and application of IFN- γ decreased fibrosis. At least part of these profibrotic and antifibrotic effects of IL-4 and IFN- γ may be directly on the proliferation and collagen synthesis of fibroblasts.

A novel cytokine, fibrosin, which has been recently cloned, together with TGF- β 1 is associated with fibrosis in murine granulomas and downregulation of both cytokines coincided with immune downregulation and reduction of granuloma sizes.

Vaccination

The best characterized vaccine model for plathelminths is the vaccination of mice with γ -irradiated cercariae of *S. mansoni*. Optimally irradiated cercariae stimulate the host's immune system and confer high levels of resistance without causing the severe pathological symptoms of schistosomiasis. They penetrate the host's skin as successfully as nonattenuated larvae do, but their migration is delayed, causing them to spend a prolonged time in the skin, lymph nodes, and lungs. Because optimally attenuated schistosomes die immaturely during their passage from the lungs to the liver of the host, pathology in the form of egg granuloma is completely circumvented. First studies testing irradiated cercariae as a possible vaccine against schistosomiasis were performed more than four decades ago. Although the experimental designs were not comparable among investigations, these early data prompted further research on the vaccine model resulting in a thorough analysis of this method of immunization.

Conditions for Immunization

The dose of irradiation used to attenuate the cercariae was recognized early on as a parameter affecting the level of resistance. At first, doses of 2.5–10 kRad were regarded as optimal. Later, presumably due to technical improvements, the positive correlation between irradiation dose and level of resistance was found to continue up to and level at a range of 24–56 kRad, decreasing gradually with doses beyond. More recently, irradiation doses of 15–20 kRad have consistently resulted in higher levels of protection than doses of 50 kRad or more.

As with other vaccination protocols, the level of resistance depends on the number of boosts with and the dose of antigenic material, in this case the number of exposures to and the load of irradiated cercariae. Studies comparing levels of protection induced by up to 8 monthly exposures demonstrated that five immunizations result in an optimal level of resistance. A 4-week interval generates best results and this regimen is commonly applied. If mice are vaccinated once, the number of immunizing cercariae does not appear to affect the level of resistance. However, the cercarial number has a significant influence in multiply vaccinated mice and when higher irradiation doses are used. Mice vaccinated with 500–1,000 cercariae achieve higher levels of resistance than do those vaccinated with 20–100 cercariae.

Employing the parasite's natural behavior, mice are generally exposed percutaneously to irradiated cercariae. The skin of the shaved abdomen, tail, or ear pinna serves as entry site. Distant sites are sometimes chosen for penetration of immunizing and challenging cercariae to avoid nonspecific local inflammatory responses. Such reactions, however, do not appear to significantly influence the level of resistance and any of the three entry sites may be used.

Protective immune responses stimulated by vaccination with irradiated cercariae are most effective 7–30 days postvaccination, with the 30-day period between vaccination and challenge considered optimal. If mice are challenged 15 weeks after exposure to immunizing cercariae, their levels of resistance are somewhat reduced.

Eighteen months postvaccination, resistance is lost in some mouse strains (CBA/Ca, BALB/c), whereas others maintain partial resistance (CF1). Thus, the immunity induced by irradiated cercariae appears to be relatively long-lasting.

The genetic background of the murine host also influences the absolute level of resistance that may be achieved. Data on resistance of C3H/HeJ (C3H) and CBA/J (CBA) mice are variable, ranking them as nonresponders or moderate responders. In contrast, C57BL/6 J (C57) mice are consistently regarded as high responders. Differences in the degree of immunity are caused, in part, by variations in the major histocompatibility complex, as was demonstrated by cross and back-cross experiments of congenic mice differing in their H-2 haplotypes. However, outbred mice are also effectively immunized by irradiated cercariae and may be more representative of natural host populations.

Interestingly, the resistance stimulated by vaccination with irradiated cercariae seems to be species-specific. Mice vaccinated with irradiated *S. mansoni* cercariae and challenged with other *Schistosoma* spp. or vice versa are not protected. However, cercariae of geographically distinct isolates of *S. mansoni* successfully cross-protect mice, indicating that the major antigens relevant to protection are common to these isolates. Similarly, no difference in the ability to stimulate resistance exists in clones of schistosomes, or in parasites that have been passaged selectively for their resistance to the host's immunity. Thus, results obtained using one *S. mansoni* strain may be extrapolated to other strains.

Although percutaneous exposure to irradiated cercariae stimulates the highest levels of resistance, mechanically transformed irradiated schistosomula may be administered instead. Advantageously, schistosomula may be stored by cryopreservation without losing their immunogenicity. The effectiveness of vaccination with irradiated schistosomula varies, however, with the route of injection. Intravenous or subcutaneous injection of irradiated schistosomula is only marginally protective, and intraperitoneal, intratracheal, and intramuscular injection rank intermediate, whereas the intradermal injection

of attenuated schistosomula induces particularly good protection against challenge infection. Intradermally administered schistosomula persist in the skin and are able to migrate to the draining lymph nodes and the lungs. Only schistosomula administered intradermally share similar migration patterns with penetrating cercariae.

Migratory Pattern of Immunizing and Challenging Schistosomes

To identify sites where the protective immunity is stimulated, the migratory pattern and the attrition site of irradiated schistosomes have been compared to those of nonattenuated parasites. Various methods were applied such as histological investigations, counting of parasites upon their exit from minced lung tissue, and detection of radio-labeled parasites by compressed organ autoradiography. Generally, the time of survival and the migratory pattern of attenuated larvae depend on the irradiation dose used (Fig. 6). A dose of 1 kRad seems to have little effect on parasite development, although an increased number of dead eggs are found. At 2–3 kRad, very few and stunted adult worms are recovered from the liver. Because the occasional eggs they produce are not viable, this dose is considered sterilizing. Doses of 4 kRad or higher do not permit survival of parasites to adulthood. Parasites irradiated with a 20-kRad dose migrate more slowly than their nonattenuated counterparts. They remain in the skin for up to one week, and thus their passage to the lungs is delayed. There, they are observed at least until day 21, at which time nonattenuated parasites have left the lungs and entered the liver. Lying within alveoli, many attenuated schistosomula seem to lose the capacity of onward migration and only a quarter of 20-kRad irradiated parasites reach the liver. Irradiation with a 50-kRad dose results in further retardation of the parasites' migration from the skin to the lungs, and only few worms are found in the liver. As early as 2 weeks after penetration, the majority of these parasites have died, leaving residual inflammatory foci. Most 90-kRad irradiated parasites fail to leave the skin, indicating that increasing irradiation doses diminish the parasites' ability to migrate through the tissues. Abnormal

Schistosomiasis, Man, Fig. 6 Impact of the irradiation dose on migration and survival of attenuated *Schistosoma mansoni* in mice

constrictions are observed in attenuated larvae as early as 6 days after 20-kRad irradiation that are not apparent in nonattenuated parasites. This impairment appears to restrict the motility of irradiated parasites and may explain their prolonged presence in the skin and lung tissue as well as the inhibition of their onward migration.

Excision experiments have been performed to determine for how long, and where within the host, attenuated parasites must be present in order to stimulate resistance. Excising the site of skin penetration within the first 4 days following exposure completely blocks induction of resistance, possibly because most attenuated parasites are removed before they are able to disseminate in the host. Removal of the penetration site between the fifth and eighth day permits the development of low but significant levels of resistance compared to nontreated mice. Skin excision thereafter fails to affect resistance. If axillary and inguinal lymph nodes draining the abdominal penetration site are surgically removed 5 days before exposure to irradiated cercariae, the level of resistance

is reduced by two-thirds. Thus, factors such as the duration of host-parasite contact, maturation of the immunizing parasite, and migration to a post-skin site appear to be relevant to the development of a protective immune response.

In vaccinated mice, the migration pattern and attrition site of nonattenuated parasites delivered as challenge infection have been investigated. In mice vaccinated with 20-kRad irradiated cercariae, the migratory pattern of challenge parasites is delayed but otherwise similar to that observed in naive mice. Challenge parasites in mice vaccinated with 50- or 56-kRad irradiated cercariae migrate even more slowly to and from the lungs. Some studies identify the skin as the major site of immune elimination, others the lungs. Differences in methods or mouse strains may cause these variable results. In both sites, inflammatory foci are observed and may be relevant to the immobilization and elimination of challenge parasites. It is generally agreed that in optimally vaccinated mice challenging schistosomes are eliminated before they reach the liver.

Although the morbidity-causing ► **host response** in the form of egg granulomas does not result from exposure to irradiated cercariae, attenuated cercariae induce inflammatory responses during their migration through the host. The extent of host tissue response depends on the irradiation dose applied to the immunizing cercariae. Whereas 50-kRad irradiated parasites induce dermatitis and vasculitis, 5- or 2.5-kRad irradiated larvae cause granulomatous foci in lungs or liver, respectively. Cercariae irradiated with 24 kRad induce more lesions than the slightly less protective 48-kRad irradiated cercariae. Unlike granulomas developing around schistosome eggs, the inflammatory foci formed around irradiated parasites appear not to harm the host, because they are not systemic and disappear with time. In fact, inflammatory foci may even benefit the host by trapping challenge parasites. As a result, migration of challenge parasites is slowed; they leave the skin or lungs later than do schistosomes in naive mice, and eventually die within such foci. Thus, focal inflammatory responses in vaccinated mice may be advantageous rather than detrimental to the induction of resistance.

Humoral Immune Responses

The role of antibodies in the protective immunity induced by irradiated cercariae was demonstrated early on by passively transferring resistance to naive mice using serum of vaccinated mice. The protective capacity is restricted to sera obtained from multiply vaccinated mice. The serum may be administered 1 h before or several days after challenge, depending on whether the skin or lung stage, respectively, is to be targeted. Serum administration by intravenous, intraperitoneal, or subcutaneous injection is equally effective. The IgG isotypes, particularly IgG₁, appear to be protective and may be enhanced synergistically by the presence of IgM.

The successful transfer of resistance prompted further analysis of the humoral immune response in vaccinated mice. Parasite-specific antibodies are detected as early as 2 weeks after vaccination. Their titers peak at 5–6 weeks and then gradually decline, but antibodies are still detectable 15 weeks after vaccination. Antibody titers are

enhanced by repeated exposure to irradiated cercariae or after challenge infection with nonattenuated cercariae, showing a typical anamnestic response.

Although the presence of antibodies is essential, as determined by the failure of B cell-depleted mice to generate any resistance, no consistent association between overall antibody titer and level of resistance is apparent. Whereas levels of resistance are not affected by the absence of IgM antibodies in X-linked immunodeficient (xid) mice, nonprotected mice of the P/N strain produce only small amounts of schistosome-specific IgM antibodies as compared to highly protected mice of other strains. Similarly, upon comparison of three mouse strains, titers of antibodies binding to crude antigen mixtures seem not to correlate with levels of resistance. In contrast, overall levels of schistosome-specific antibodies are greater in mice vaccinated with 15- or 20-kRad irradiated cercariae than in less protected mice vaccinated with 40- or 50-kRad irradiated cercariae. Idiotypic regulation may also be important, because anti-idiotypic immunization suppresses the development of resistance. Therefore, antibody specificity rather than quantity appears to be relevant to protective immunity.

In order to examine antibody specificity of vaccine sera, surface-labeled or metabolically labeled antigens of schistosomes have been immunoprecipitated. Although these studies differ in irradiation doses, mouse strains and parasite stages used, various antigens having molecular mass of 15, 17, 19–20, 22–23, 32, 38, 43–45, and 92–94 kDa are consistently detected. A direct comparison of two mouse strains (C57 and C3H) as well as three irradiation doses (5, 25, and 50 kRad) using immunoprecipitation failed to demonstrate differences in the pattern of antigens recognized.

The antibody specificity in an array of different vaccine sera has been analyzed by immunoblot, probing whole parasite extracts. Antigens of 22–23, 28, 31–32, 70, and 97 kDa were identified as the integral membrane protein Sm23, glutathione S-transferase (GST), triose-phosphate isomerase (TPI), cathepsin B, hemoglobinase, ► **heat shock protein 70 (HSP70)**, and ► **paramyosin**,

Schistosomiasis, Man, Fig. 7 Antigens recognized by lymphocytes derived from draining lymph nodes of mice vaccinated with irradiated cercariae of *Schistosoma mansoni*. The experimental groups of mice differed in the degree of protection achieved against a challenge infection. Proliferation assays stimulating lymphocytes of axillary lymph nodes with purified native or recombinant antigens served to determine the intensity of antigen recognition by lymphocytes. Font size indicates relative intensity. Lymphocytes of once-vaccinated mice proliferate more strongly in response to these antigens than do those of

multiply vaccinated mice. ^aIn response to paramyosin, lymphocytes of C57BL/6 J mice vaccinated with 15-kRad irradiated cercariae produce IL-2 but not IL-4. ^bIn the presence of heat shock protein (*HSP70*), IL-2 production by lymphocytes of C57BL/6 J mice vaccinated with 15-kRad irradiated cercariae decreases after repeated vaccination, while IL-4 production increases. ^cSm32 is also known as hemoglobinase. ^dGlutathione S-transferase (*GST*). ^eTriosephosphate isomerase (*TPI*). ^fIntegral membrane protein Sm23

respectively. In contrast to other studies, immunoblot analysis demonstrated that both the irradiation dose used to attenuate cercariae as well as the genetic background of the mice influence the titer and the specificity of antibodies to particular antigens (Fig. 7).

Cellular Immune Responses

T cells are essential for the induction of protective immunity in this model, because athymic mice fail to develop resistance following exposure to irradiated cercariae. Proliferative responses of lymphocytes to schistosomal antigens peak during the first 2 weeks after vaccination, waning after the fourth. Lymphocytes derived from draining lymph nodes respond considerably more strongly

than those derived from spleen. The relevance of regional rather than systemic stimulation is supported by the observation that attenuated parasites release significant amounts of antigenic material during their passage through skin, lymph nodes, and lungs. As a result, the time and site of lymphocyte priming coincide closely with the parasites' migration, i.e., proliferation is observed first in skin-draining and later in lung-draining lymph nodes. Because greater amounts of antigens are released over an extended period in axillary and inguinal lymph nodes of vaccinated mice than in other lymph organs or as compared to mice infected with nonattenuated cercariae, lymphocytes in these lymph nodes, as well as in mediastinal nodes, proliferate most strongly. In

contrast, no proliferation is detected in cells from brachial, periaortic, or mesenteric nodes. In primed lymph nodes, the number of T cells increases relative to that of B cells. The irradiation dose used to attenuate the cercariae has a profound effect on their lymphostimulatory capacity, because it affects their migratory pattern. Whereas longer-lived 20-kRad irradiated cercariae stimulate extensive proliferation in draining lymph nodes, 50-kRad irradiated cercariae induce modest responses, and nonprotective 80-kRad irradiated parasites that fail to leave the skin penetration site induce only a transient increase in cell number. Therefore, optimally attenuated parasites deliver themselves to sites where antigen processing is intense. While remaining there for a prolonged period, they release antigenic material priming lymphocytes required for successful vaccination.

Removal of draining lymph nodes before vaccination reduces the level of resistance. Because removal a week after vaccination eliminates priming parasites as well as primed lymphocytes, only low levels of immunity develop. Lymphadenectomy at later times does not abrogate resistance, because primed lymphocytes have begun to circulate. The pool of these peripheral lymphocytes expands vigorously, reaching its maximum 3–4 weeks after vaccination, and persists at an elevated level. Simultaneously, numerous activated lymphocytes infiltrate the pulmonary ► [parenchyma](#) and airways. Lymphocytes of the draining lymph nodes as well as those recruited to the lungs participate in the induction of immunity. Successful vaccination correlates with percutaneous exposure or intradermal injection of attenuated parasites, because only these routes of administration allow the parasites to migrate through the draining lymph nodes as well as through the lungs.

T cell subsets have distinct effects on the induction of immunity, as demonstrated by depletion studies. Depletion of CD4⁺ T cells decreases the level of resistance. In fact, resistance to challenge falls below that observed in athymic mice, if mice are depleted of CD4⁺ T cells before vaccination. In contrast, depletion of CD8⁺ T cells reduces

morbidity and enhances resistance to a level higher than that observed in nondepleted control mice. The ratio of reactive CD4⁺ T cell subsets is shifted by the number of exposures to irradiated cercariae. Cytokines produced by Th1 cells predominate in once-vaccinated mice and dissipate in multiply vaccinated mice with a concurrent increase in cytokines produced by Th2 cells. Repeated vaccination results in an overall decreased proliferative response. Both observations might explain why CD4⁺ T cells are essential to the induction of resistance in once-vaccinated mice but appear less critical in twice-vaccinated mice.

The Th subsets participating in the induction of protection were further characterized by cytokine studies. Upon in vitro stimulation, lymphocytes of mice vaccinated with the more protective 15-kRad irradiated cercariae secrete significantly more of the Th1 cytokine IFN- γ than do mice vaccinated with less protective 50-kRad irradiated cercariae, and lymphocytes of the latter mice produce far more IFN- γ than nonprotected P/N mice. Further, in vaccinated IFN- γ -receptor knockout mice or in vaccinated mice depleted of IFN- γ by antibody treatment, protective immunity is abrogated by about 50–90 %. In such mice, mRNA expression of Th2 cytokines, such as IL-4, IL-5, IL-10, and IL-13, is elevated and that of Th1 cytokines is diminished. The kinetics of IFN- γ production in vaccinated mice coincides with the migratory pattern of the immunizing parasites. This cytokine is initially produced in the skin within 24 h after vaccination and by lymphocytes obtained from axillary and inguinal lymph nodes 4 days later, peaking 2 weeks after vaccination. At this time, lymphocytes from mediastinal lymph nodes only begin secreting IFN- γ , while lymphocytes obtained by ► [bronchoalveolar lavage](#) secrete high titers of IFN- γ , coinciding with macrophage activation. In contrast, depletion of cytokines produced by Th2 cells, such as IL-4 and IL-5, does not affect resistance in vaccinated mice. Neither IgE nor eosinophils appear to be required in vaccinated mice. Therefore, secretion of Th1 cytokines correlates with the degree of vaccine-induced immunity and Th2-associated

antibody responses in multiply vaccinated mice enhance protection.

A potent inducer of IFN- γ production is IL-12. This cytokine affects the differentiation of Th cells by stimulating the expansion of Th1 cells while suppressing the differentiation of Th2 cells. In mice vaccinated once with irradiated cercariae, administration of IL-12 enhances the vaccine-induced protection against a challenge infection by about 20 %. At the same time, mRNA levels of IFN- γ and IL-12 increase, while those of the Th2 cytokines, IL-4 and IL-5, eosinophilia, and titers of IgE are reduced. Although the responses of the Th2 subset prevail in mice multiply vaccinated with irradiated cercariae, exogenous IL-12 is capable of further augmenting the degree of protection, even achieving complete protection in some individuals. In such multiply vaccinated mice, IL-12 appears to enhance the production of parasite-specific antibodies, particularly those isotypes that are Th1-associated. Studies on IL-12 knockout (IL-12KO) mice vaccinated with irradiated cercariae confirm the fundamental role this cytokine plays in generating protective immune responses. Vaccinated IL-12KO mice produce cytokines and antibody isotypes that correspond to the Th2 phenotype and, possibly as a result, develop a significantly greater worm burden from a challenge infection than do their wild-type counterparts. Inflammatory foci in the lung of vaccinated IL-12KO mice have a looser appearance and contain more eosinophils than do those in wild-type mice and, as a result, may be less efficient in blocking the migration of challenging schistosomes. In IL-12KO mice, recombinant IL-12 permanently restores the ability to generate protective Th1 responses. If this cytokine is administered during the first week after vaccination, such knockout mice produce levels of IFN- γ , develop inflammatory foci around challenge larvae, and achieve levels of protection comparable to those of wild-type mice. Thus, IL-12 serves an important role in inducing protective Th1 responses in mice vaccinated with irradiated cercariae. On the other hand, vaccinated IL-10-deficient mice generating an intermediate Th1/Th2

response develop higher levels of protection than do wild-type mice, indicating that IL-10 may downregulate the protective immune response in vaccinated mice.

The importance of Th1 responses is further evidenced by studies on the delayed type hypersensitivity (DTH) (type IV). Vaccinated mice exhibit a profound DTH reaction to soluble schistosomal antigens *in vivo*, starting 10 days after exposure to irradiated cercariae and peaking 1 week later. Significantly decreased DTH reactivity coincides with reduced levels of resistance in athymic mice, P/N mice, or in mice depleted of CD4⁺ or IL-2-receptor bearing cells. On the other hand, mice deficient in mast cells or IgE production develop levels of resistance comparable to that of nondeficient controls. The immediate hypersensitivity (type I) response observed in mice of the P/N and C57 strains does not differ. Delayed but not immediate hypersensitivity appears to be relevant to the immunity induced by irradiated cercariae.

Inflammatory foci in the skin and lungs of vaccinated mice participate in the development of protection. Upon challenge infection of multiply vaccinated mice, ICAM-1 mediates an early accumulation of mononuclear cells in the skin and local production of nitric oxide. Similarly, large numbers of Th cells infiltrate the lungs after vaccination. Virtually all express high levels of the CD44 molecule, identifying them as effector/memory cells. Because binding of CD44 to its ligand, which is present in the lung, promotes cell aggregation and cytokine release, it may serve to initiate and maintain inflammatory responses. Upon challenge, the cellular composition of these foci is characteristic of a DTH response. The cells are found in tightly compact aggregates. Whereas in vaccinated IL-10-deficient mice tight inflammatory foci develop, in vaccinated IL-12KO or IFN-gamma-receptor-KO mice, cell aggregates are much larger and looser, concurrent with a reduction in immunity. In addition, IFN- γ affects the expression of inducible nitric oxide synthase, which is associated with inflammatory foci developing around challenge schistomula in the lungs of vaccinated mice.

Thus, challenge parasites appear to be trapped in compact pulmonary inflammatory foci of vaccinated mice.

Candidate Vaccine Antigens

The antigens that are recognized by the humoral compartment of mice vaccinated by irradiated cercariae also induce lymphocyte proliferation in these mice (Figs. 8 and 7). The response to this array of antigens, consisting of Sm23, GST, TPI, cathepsin B, Sm32, HSP70, and paramyosin, has been further characterized by quantifying levels of antigen-specific isotypes as well as their

lymphostimulatory capacities in different groups of vaccinated mice. Experimental groups of mice achieve various degrees of resistance due to their genetic background, the number of exposures to irradiated cercariae, and the irradiation dose with which the immunizing cercariae had been attenuated. Vaccinated C57 mice develop a higher degree of protection than do CBA mice which can be further enhanced by multiple exposures to irradiated cercariae. Those mice that are vaccinated with 15-kRad irradiated cercariae are better protected against challenge infection than those vaccinated with 50-kRad irradiated cercariae.

Schistosomiasis, Man, Fig. 8 Antigens recognized by antibodies of mice vaccinated with irradiated cercariae of *Schistosoma mansoni*. The experimental groups of mice differed in the degree of protection achieved against a challenge infection. Specific antigens were identified by immunoblot analysis. Enzyme-linked immunosorbent assay (ELISA) using purified native or recombinant antigens served to determine the intensity of antigen recognition by antibodies. Font size indicates relative intensity. Generally, levels of antibodies specific for these antigens are higher in multiply vaccinated mice than in once-

vaccinated mice. ^aAntibodies of vaccinated CBA/J mice detect heat shock protein (HSP70) only in ELISA, not in immunoblot. ^bSm32 is also known as hemoglobinase. ^cIgM antibodies dominate the response to glutathione S-transferase (GST) and about half recognize carbohydrate epitopes. ^dTriosephosphate isomerase (TPI) is solely recognized by once-vaccinated mice. ^eIn response to the integral membrane protein Sm23, C57BL/6 J mice vaccinated with 15-kRad irradiated cercariae produce also antibodies of the IgG_{2b} isotype that are not detected in other experimental groups

GST is recognized by the humoral and the cellular immune compartment of all groups of vaccinated mice. Protective sera, passively transferring resistance, contain particularly high titers of IgM antibodies to GST. These antibodies bind predominantly to carbohydrate epitopes of this antigen. GST stimulates proliferation of Th2 cells in both C57 and CBA mice, whereas proliferation of Th1 cells is restricted to vaccinated CBA mice. Antibodies specific for the integral membrane protein Sm23 are present in all tested vaccine sera. The highest levels of protection in mice multiply vaccinated with 15-kRad irradiated cercariae coincide with the highest levels of Sm23-specific antibodies. Highly protective sera contain large quantities of IgG_{2b} antibodies binding to Sm23. In contrast, the humoral and cellular responses to recombinant TPI are restricted to once-vaccinated mice in this vaccine model. Thus, protective vaccine sera derived from mice immunized with irradiated cercariae appear not to contain TPI-specific antibodies. The digestive enzymes, Sm32 and cathepsin B, are recognized by mice vaccinated with 15-kRad but not 50-kRad irradiated cercariae. Only worms that are able to survive to the hemoglobin-digesting stage seem to induce antibody production to these developmentally regulated antigens. The humoral and cellular recognition of Sm32 is strain-specific, i.e., limited to vaccinated CBA mice. In contrast, HSP70 is predominantly recognized by vaccinated C57 mice. Strong responses of both immune compartments coincide with the highest level of resistance in this strain. In highly protected mice, the response to HSP70 appears to shift from a mixed Th1/Th2 cell population to an exclusive Th2 cell population upon multiple vaccinations. The highest levels of anti-paramyosin antibodies correlate with the lowest degree of protection in vaccinated CBA mice. Although vaccinated C57 mice fail to produce paramyosin-specific antibodies, a distinct cellular response to paramyosin is associated with a high degree of immunity in these mice. Factors such as the irradiation dose used to attenuate the immunizing cercariae, the genetic background of the host, and the number of vaccinations have distinct effects on the recognition of individual antigens in this vaccine model.

Conclusions

The results of extensive studies on the irradiated cercariae vaccine model demonstrate the importance of analyzing diverse aspects of the immune responses that are induced by attenuated parasites. They allow us to begin to understand the complex mechanisms that are involved in generating vaccine-induced protection against plathelminths. Conditions for immunization, such as irradiation dose, number of cercariae, route, site, and schedule of application, have been compared and optimized. Further, the migratory pattern and attrition site of immunizing and of challenge parasites have been outlined. The compartments of the host's immune system that participate in the induction of protective immunity have been elucidated. This has initiated an analysis of where, when, and how the immune compartments interact. Subsequently, antigens were identified that stimulate humoral as well as cellular immune responses of vaccinated mice. As a result, the complex kinetics of multifaceted immune response to irradiated cercariae are being increasingly understood and may facilitate the development of a vaccine against schistosomes. It will likely consist of a cocktail of antigens in order to address the heterogeneous responsiveness to particular antigens among a majority of individuals to be protected. It may need to be administered in a way that mirrors the efficient mode of antigen presentation by moderately irradiated cercariae.

Planning of Control

Intestinal and urinary schistosomiasis may cause gross pathology and shorten the human host's life expectancy. Worm load is recognized as a major determinant of the severity of the disease. For a long time, the measures available for the control of schistosomiasis were water management, especially in connection with water impoundments and irrigation schemes, rather inefficient use of molluscicides, safe excreta disposal, health education, and less than satisfactory treatment. The introduction of oxamniquine has rendered

infections with *S. mansoni* treatable and that of praziquantel has radically improved the treatment of all forms of schistosomiasis. Both drugs are well tolerated and simple to use.

Molluscicides still pose problems: copper salts, though cheap, are not sufficiently effective, while niclosamide, though highly effective, is expensive and associated with strong nontarget effects on the aquatic fauna. Much can be achieved with appropriate water management and other forms of environmental management.

Biological methods of snail control, e.g., snail pathogens and the replacement of host species by nonsusceptible snail species, are being explored but their nontarget effects need to be assessed very carefully before a wider use may be contemplated. The provision of safe water supplies is an important factor in reducing the transmission of schistosomiasis.

Currently the primary objective of schistosomiasis control is the reduction or elimination of morbidity. Appropriate operational approaches for the attainment of this objective are available. However, control programs offer a reasonable prospect of success only if they have sufficient and well-qualified manpower, and organizational/managerial structures capable of ensuring correct planning, smooth implementation, and continuous evaluation of operations and results. A key factor for success is local and national commitment to such a program, expressed in adequate financial resources to maintain it without external assistance. The strategy of schistosomiasis control consists, essentially, of three phases:

1. A planning period devoted to the collection and analysis of epidemiological baseline data, the determination of feasible control approaches, the preparation of a master plan of action, the allocation of resources, and training.
2. An intervention period during which intensive operations are conducted, aimed at reducing as rapidly as possible the reservoir of infection

Schistosomiasis, Man, Fig. 9 Targets and approaches for the control of human schistosomiasis

and curbing transmission. Treatment will be instrumental during this phase which is usually shorter than the first.

3. A maintenance phase during which the gains of the second phase are to be consolidated and safeguarded and, if possible, a further reduction of disease prevalence and intensity of infection are achieved. Apart from the environmental management activities, this phase will be less demanding in resources than phase 2, and most of the diagnostic and therapeutic maintenance effort will be the responsibility of the general health-care services which undertake the bulk of surveillance and monitoring.

Targets for Intervention

Infection results from the active transdermal invasion of the free-swimming cercariae. These originate from the waterborne miracidium which emerges from the egg and develops further in a suitable aquatic snail host. Targets of intervention (Fig. 9) are the infected human host, the snail

intermediate host, and the infection cycle. Suitable approaches to control consist of the detection and treatment of cases; the safe disposal of excreta; the use of safe water for drinking, washing, bathing, and swimming; and snail control through environmental management.

Schistosomulum

As the free-swimming freshwater ► [cercariae](#) of ► [Schistosoma](#) penetrate the host's skin they lose their tails and become schistosomules (► [Schistosomiasis, Animals](#), ► [Schistosomiasis, Man](#)).

Schizogony

Name

Greek: *schizis* = division, *gone* = generation, production.

In addition to ► [sporogony](#), there is another asexual phase in the life cycle of ► [Coccidia](#) giving rise to generations of schizonts (syn. meronts) and merozoites. Some of the latter initiate ► [gamogony](#) leading to ► [syngamy](#). The ► [zygote](#) initiates an asexual reproduction leading to the production of numerous infectious sporozoites. In ► [microsporidia](#) schizo-merogony also occurs.

Schizont

Asexual stage in ► [coccidia](#) that gives rise to motile merozoites that enter other cells. Schizonts (Greek: *schizein* = dividing) are thus also called meronts (Greek: *meros* = portion).

Schizotrypanum

Subgenus of the genus *Trypanosoma* with the type species ► *T. cruzi*. The trypomastigotes of this subgenus are always C-shaped, have a large kinetoplast, and they reproduce intracellularly via amastigotes.

Schmallenberg Virus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

After the spreading of the ► *blue tongue virus* epidemics (serotype 8) in most European

countries in the years 2006–2009 being transmitted by midges (e.g., ► *Culicoides obsoletus* and other *Culicoides* species) and killing ~4 % of infected cattle, up to 80 % of sheep in 18 countries in Central Europe were hit in the years 2011 and 2012 by the occurrence of the so-called Schmallenberg virus. This virus was named by the German Central Institute for Animal Health after a small town in western Germany and identified as a member of the Simbu serogroup of the so-called *Orthobunya* viruses. This virus introduced only mild symptoms in adult cattle, sheep, and goats, but led to severe damages in fetuses and/or newborn animals of these ruminants. Although there was no risk for human health, severe losses in farm animals led to a significantly enhanced observation and establishment of similar methods like the fight against the ► *blue tongue virus* epidemics. These methods of isolation of infected animals and treatment of potential hosts with surface insecticides led to a stop of the propagation of this virus, which apparently was also transmitted by ► *midges* of the genus ► *Culicoides*. The newly developed diagnosis method (real-time PCR) by the German Friedrich-Löffler-Institute (Riems) helped to separate infected from uninfected ones.

Occurrence:	Belgium, Denmark, Germany, England, France, Italy, Luxembourg, the Netherlands, Spain, Switzerland
Hosts:	Ruminants (sheep, cattle, goats, wild deer)
Symptoms of disease:	Adult animals: mild symptoms (loss of appetite, increase of body temperature, diarrheas, reduction of milk production (>50 %)) disappear after a few days or remain (if slight) unrecognized. Pregnant animals suffer from abortion
Morbidity:	Low in case of adult animals, extremely high in fetuses
Mortality:	Extremely high in fetuses, rare in adults
Agents of disease:	<i>Orthobunya</i> virus containing single-stranded RNA (3 segments)
Mode of transmission:	Bites of midges: e.g., <i>Culicoides obsoletus</i> and <i>C. chiropterus</i>
Vaccination:	Shortly on the market a vaccine by Wernicke et al. (2013)

Schüffner, Wilhelm (1867–1949)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Wilhelm Schüffner (Fig. 1), a German physician who worked for a Netherlands company (1897–1923) in the Sumatra colonies of The Netherlands, investigated intensively the malaria disease and tried to ameliorate the working conditions of the local people by the development of natural methods to control the spreading of the malaria. During these studies he noted a change in *Plasmodium vivax* infected red blood cells. This phenomenon that infected red blood cells appear pale and

are sprinkled with tiny reddish condensations which were later called ► **Schüffner's dots** and are easy means to differentiate the specimens of *P. vivax* and *P. ovale* from *P. falciparum* (see micrographs of ► *Plasmodium* species). Thus Schüffner was a man at the frontline in the fight against malaria as man killing disease became unforgotten in research literature. He was awarded the member of the Royal-Netherland Society of Science in 1926 and the member of the German Academy of Science (Leopoldina at Leipzig) in 1935.

Sea Fleas

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Some of the over 6000 species of so-called Amphipoda are living as parasites. Especially members of the family Cyamidae are parasites of cetaceans.

Secernentea

Synonym

Phasmodia.

Classification

Class of ► [Nematodes](#).

General Information

► [Phasmods](#) are present posterior to the anus; hypodermis uni- to multinucleate; ► [cuticle](#) with 2–4 layers; males have only a single ► [testis](#) and are commonly endowed with caudal ► [alae](#)

(known as copulatory bursa); somatic setae or papillae absent on females; amphids usually open to exterior through pores located dorsolaterally on lateral lips or anterior extremity; cephalic sensory organs are porelike, found on lips (16 in 2 circles with 6 inner and 10 outer ones).

Second Endoplasmic Reticulum of Apicomplexa

This structure abbreviated as ► [SERA](#) is found adjacent to the surface of penetrated ► [Plasmodium](#) stages. It is involved in an alternative secretory pathway and is formed by the fusion of normal ER plus the membranes of ► [rhoptries](#) and ► [micronemes](#).

Secondary Antibody

Synonyms

Conjugate, Anti-Immunoglobulin antibodies.

General Information

In indirect serological methods, which are common for serodiagnosis of parasitic infections, the antigen-specific antibody is detected by use of a secondary antibody. The secondary antibody (anti-immunoglobulin antibody) is available as species, class, subclass, or domain-specific. It can be used as a general reagent for screening of all antibodies or as a selective reagent to identify one type of antibody class or molecule. Different degrees of cross-reactions occur at all levels between subclasses, classes, and species and may decrease the specificity of an assay. A reduction of cross-reactions is possible by use of cross-absorbed preparations. The conjugate provided by suppliers should be specific for the stated isotype. Labeling of the secondary antibody is mainly by enzymes (horseradish peroxidase,

alkaline phosphatase), fluorochromes (fluorescein, rhodamine), or biotin. The choice of label depends on the technique used, the available detection system and the field of application.

Characteristics

Fluorescein-labeling is unstable and does not allow a repeated reading or long-term storage of the preparations. The conjugated enzyme and its substrate are chosen for sensitivity and convenience. In general, alkaline phosphatase is simpler to use but horseradish peroxidase is probably more sensitive.

Secondary Cyst Wall

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes an amorphous layer formed by degenerated host cells that surround the ► [tissue cysts](#) of some species (e.g., ► [Sarcocystis ovifelis](#), ► [Besnoitia](#) species, and ► [Trichinella spiralis](#) and related species in a late stage).

Secretion

The process of emitting a substance from a cell (► [Exocytosis](#)) by mechanisms similar to those for the internalization of materials (► [Endocytosis](#)). ► [Platyhelminthes](#)/► [Integument](#), ► [Ticks](#)/Intestine and Food Uptake, ► [Insects](#)/Intestine and Food Uptake.

Secretory Proteins

In asexual apicomplexan motile stages (e.g., merozoites, sporozoites, ► [tachyzoites](#),

► [bradyzoites](#)) various apical organelles secrete proteins (► [Dense Bodies](#), Dense Granule Protein, ► [Rhoptries](#), ► [Micronemes](#)), which are discharged, and reach the surface of the stages (► [Apicomplexa](#)/► [Host Cell Invasion](#)).

Secretome

This system transports parasite proteins to the ► [Maurer's clefts](#) (MC) – resembling Golgi-lamella – in *Plasmodium*-infected red blood cells via 2 ways:

1. Vesicles are secreted from the lumen of the parasitophorous vacuole, which join the MC.
2. Proteins are translocated across the vacuolar membrane into host cell cytosol and become associated with the cytoplasmic face of the MC.

Both processes are steered by a host-targeting signal (HT) and finally lead to transport of parasite protein into the host cell.

Sedimentation

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This is a method to isolate larger eggs of trematodes (more than 50–60 µm in length) (e.g., those of *Fasciola*, ► [Schistosoma](#)), of nematodes (e.g., *Ascaris*), of ► [Acanthocephala](#) and ► [Pentastomida](#), while smaller-sized eggs (smaller than 50 µm) or even oocysts of coccidians will only be poorly determined by this method, if larger numbers occur. In these cases, other concentration methods have to be used, e.g., ► [S.A.F.C.](#), ► [M.I.F.C.](#), and/or ► [flo-tation](#). The sedimentation method uses the following steps:

1. 5–10 g feces are mixed with 100 ml tap water (for *Schistosoma*-suspected feces use a physiological saline, which avoids hatching of miracidium larvae).
2. Larger particles are extracted by sieving the fluid.
3. The remnant solution is filled into a glass cylinder and left to settle for about 30 min.
4. Afterward, the supernatant fluid is slowly decanted and filled up with fresh water respectively saline.
5. This process is repeated until the supernatant fluid appears widely clear.
6. After a final decanting of the supernatant fluid, the sediment material is repeatedly microscopically inspected for parasitic stages.

Sentinel Animal

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Animal that might be used as an indicator of the presence of a given pathogen in a defined area, when it is experimentally exposed to this pathogen.

Septata intestinalis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Latin: *septum* = dividing wall;
intestinalis = belonging to the intestine.

General Information

The specimens of this species penetrate human cells of the nose, lung, intestine, and those of the urogenital system. Although this species had already been described in the year 1993, its life cycle is still unknown. Spores of this species were found in 2.2 % of all investigated diarrheic stools of AIDS patients. Treatment with albendazole (2 × 400 mg per day) for 4 days led to the disappearance of the symptoms of the disease and to a stop of the excretion of spores within the feces. See ► [Microsporidia](#).

Sequestration

Some parasites retire from regions with active immune attacks (e.g., ► [Malaria](#) parasites do it by adhesion at walls of inner blood vessels or cysticerci of ► [tapeworms](#) stay in the brain).

SERA

Serine-repeated antigen of ► [Plasmodium](#) merozoites.

Sergentomyia

Genus of the mosquito family Phlebotomidae.

Seroconversion

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The term seroconversion describes the development of antibodies in previously negative patients or in groups of a given population in a defined

time frame as a result of a natural infection or by application of a vaccine. The term “rate” confers on the number of people involved when, e.g., controlling vaccination programs. In the case of ► *Toxoplasma gondii* infections of previously noninfected pregnant women, a seroconversion may be a sign that the fetus might be endangered. In these cases chemotherapy should be discussed depending on the antibody level and the stage of gravidity.

Serology

Ingrid Reiter-Owona and Hans Martin Seitz
Institut für medizinische Parasitologie,
Universität Bonn, Bonn, Germany

Synonyms

Antibody detection; Immunodiagnosis;
Serodiagnosis

General Information

Serology in general, which describes changes in the immunological potency of body fluids after infection with a specific pathogen under diagnostic aspects, has gained increasing importance over the last 20 years for microbiology. Serology of parasitic infections, in particular, gained much from the in vitro cultivation of parasites and the production of monoclonal antibodies. Both techniques together improved the knowledge of parasitologists on stage-specific antigens and antibodies and their relevance for immunodiagnosis. A variety of potential ► [immunoassays](#) were developed to measure the change in kinetics and concentration of parasite-specific antibodies. The

technical developments favoured the ELISA-system, as it needs only minor quantities of reagents and it can equally be used for antigen and antibody detection. The application of highly specialized test systems showed clearly that serological values are never absolute but a function of the type of antigens presented and antibody classes detected. Whereas IFAT antibodies are predominately directed against the surface-membrane-associated parasite antigens, ► [ELISA](#) antibodies are usually directed against soluble antigens of a complex mixture or already predefined soluble antigens. Traditional serology was primarily used to demonstrate a specific antibody response in symptomatic individuals. Today, epidemiological studies can provide fast knowledge on the distribution and host specificity of parasites as demonstrated for *Neospora* (*Hammondia*). Standardization and quality control of test systems is now regarded as an essential requirement. There is evidence that many difficulties in antigen production and standardization may be solved with the exciting advances in molecular biology and biotechnology. Specific detection systems for the quantification of parasitic antigens in body fluids, which allow a non-invasive diagnosis at low costs, are currently favoured, and may reduce the need for indirect diagnosis. Also, the introduction of the polymerase chain reaction (PCR) as diagnostic tool has dramatically lowered the level for direct parasite detection, so far determined by microscopic examination only.

The development in serodiagnostic methods, however, which are easy and cheap to use in countries with a population at high risk in contracting parasitic infections, has been neglected.

The value of serology for clinical diagnosis depends on the interaction of the specific parasite and the host (Table 1). Parasites not only stimulate the humoral immune response as part of the immunological defence mechanisms but are also capable of evading the immune response to

exposed epitopes. Some parasitic infections are associated with the production of non-specific serum antibodies (IgM in trypanosomiasis and ► [malaria](#), IgG in malaria and leishmaniasis) or the production of autoantibodies (Chagas' disease, malaria, onchocercosis). Each serological assay has advantages or disadvantages in regard to sensitivity, specificity, or cost-effectiveness. The combination of at least two different test systems will increase the diagnostic reliability.

Clinical Relevance

Conventional parasitological diagnosis relies upon the visualizing of the parasites or their products of reproduction in body fluids, excreta, or tissue. Because of their often long and complicated life cycles, parasites may be undetectable during the prepatent period. Thereafter, they may occur intermittently, in low grade or be frequently absent from body fluids (*Trypanosoma* spp., microfilariae), from excreta (► [Ascaris](#), ► [Strongyloides](#), *Schistosoma* spp., *Fasciola* spp., ► [hookworms](#)), or hidden within/between host cells or tissue (*Leishmania* spp., *T. cruzi*, *Toxocara* spp., *Trichinella* spp.).

While serology is an important diagnostic method in many situations, in other situations it is not helpful (Table 1). A basic finding is that parasites which are either free-living throughout their whole life cycle within the gut (*Entameba dispar*, ► [Lambli](#) *intestinalis*, *Cryptosporidium parvum*, *Cyclospora*, *Enterobius*, ► [Trichuris](#), *Taenia* spp.) or remain restricted to the skin (*L. tropica*, ectoparasites), epithel (*Acanthameba*), or mucosal surface (*Trichomonas* spp.), do not induce a strong humoral immune response. Antibody detection is either negative or at a low level or the seroprevalence rate exceeds the number of parasite carriers. Here, serology is not helpful for the clinical diagnosis.

The acute phase with severe clinical symptoms precedes the antibody formation after infection with *Plasmodium* spp., *Babesia* spp., *Theileria* spp., *Sarcocystis* spp., and *Trichinella* spp. Parasitaemic individuals have a delay in raising their antibody response. Here, diagnosis of acute infection relies primarily upon parasite detection and/or clinical parameters. The finding of significant antibody titers in asymptomatic, untreated individuals indicates a carrier state since parasitaemia drops below the detectable level long before antibodies disappear.

Serology is of main advantage for the diagnosis of parasitic infections which are characterized either by larval migration through host tissues (► [Toxocara](#) spp., *Ascaris* spp., *Strongyloides*, *Schistosoma* spp., *Fasciola* spp., filariae), by ► [encystation](#) (► [Toxoplasma gondii](#), ► [Sarcocystis](#) spp., *Trichinella* spp., *Echinococcus* spp., *Cysticercus* spp.), or inter-/intracellular residence (*Leishmania* spp., *Entameba histolytica*, *Trypanosoma cruzi*, *Neospora* spp.) in the host tissues during ► [chronic infection](#). Here, diagnosis is based on serological techniques and is virtually the only practicable way of screening for infection.

The humoral immune response to parasitic infections involves almost all antibody classes and subclasses. Most ► [helminth](#) infections are chronic and have an extended subclinical phase. When clinical symptoms occur the IgG response is predominant. Screening for infection with total Ig- or IgG-conjugates (enzyme or FITC labelled) is efficient in most cases. The reactivity of the IgG4 subclass, which is elevated in chronic helminth infections, is highly specific and enables a species-specific diagnosis for many parasites by ELISA.

Detection of specific IgM antibodies is essential for an early diagnosis of toxoplasmosis and may improve the early diagnosis of ► [sleeping sickness](#) and Chagas' disease. However, IgM persistence at low level during chronic *Toxoplasma*-infection raises many questions.

Serology, Table 1 The serology of various parasites in the treatment of disease. Antibody detection is either by ELISA, IIFAT, IHAT, or other test systems. The common strategy is to choose a test system of high sensitivity for primary antibody screening. Positive test results, dependent upon the level of cross-reactivity with other parasites and the geographical origin of the patient, have to be confirmed by either more specific assays (recombinant antigens, WB) or parasite detection

Disease	Parasite	Prepatent period	Serology
Amoebiasis	<i>Entamoeba histolytica</i>	Days to weeks	Is of main value for detection of amoebic liver abscess with an approx. sensitivity of 100 % when tested a few days after onset of disease; positive serology is also indicative of an invasion of the gut by the parasite; background reaction is possible in endemic areas; antibodies may persist after therapy
Babesiosis	<i>Babesia</i>	1–3 weeks	Is not for acute infection!
	<i>B. ovis/divergens</i>		Is useful, however, when parasitaemia is at a low level or transient and for epidemiological studies
	<i>B. microti</i>		
	<i>B. canis</i>		
	<i>B. equi/caballi</i>		
Chagas's disease	<i>Trypanosoma cruzi</i>	2–4 weeks	Is not reliable for screening during acute infection; is of great value for screening during chronic infection and for blood transfusion screening
Cysticercosis	<i>Taenia solium</i>	60–70 days	Is a valuable tool for the diagnosis of neurocysticercosis in symptomatic/asymptomatic cyst carriers; a positive result has to be confirmed by a species-specific test system; negative serology occurs in approx. 30 % of individuals with low cyst burden
Echinococcosis		Months to years	Is of great value for the differential diagnosis in cyst carriers; seropositivity may be low in patients with cystic echinococcosis (70–95 %) but is normally high in patients with alveolar echinococcosis (95–100 %); positive results in a genus-specific screening test are confirmed with an <i>E.-multilocularis</i> -specific ELISA; serology is of limited value in monitoring the course of disease after specific therapy or post operatively
Cystic	<i>Echinococcus granulosus</i>		
Alveolar	<i>Echinococcus multilocularis</i>		
Fascioliasis	<i>Fasciola hepatica</i>	2–4 months	Positive test results in symptomatic patients indicate infection; eggs may be undetectable or excreted in low quantities; first antibodies appear 4–8 weeks after infection and return to negative values 3–6 months after successful therapy
Filariasis			Is of value for a first screening for infection;
Onchocerciasis	<i>Onchocerca volvulus</i>	12–20 months	specific antibodies can be expected a few weeks after infection; most test systems available have high sensitivity and low specificity; positive results in exposed/symptomatic individuals must be confirmed by parasite detection; negative serology practically excludes infection
Lymphatic Filariasis	<i>Wuchereria bancrofti</i>	3–7 months	
	<i>Brugia malayi</i>		
	<i>B. timori</i>		
Loiasis	<i>Loa loa</i> <i>Mansonella spec.</i>	6–12 months	

(continued)

Serology, Table 1 (continued)

Disease	Parasite	Prepatent period	Serology
Leishmaniasis			
Visceral (VL)	<i>Leishmania infantum</i> , <i>L. donovani</i> , <i>L. chagasi</i>	Days to months	Is not of practical value for diagnosis of CL as low antibody titers occur only in a proportion of patients; in ML, antibody response is more consistent; high antibody levels are common in patients with generalized infection and clinical symptoms; antibody detection may be positive in asymptomatic individuals; treatment can be monitored by detection of antibodies which decrease slowly after therapy
Mucosal (ML)	<i>L. braziliensis</i> complex		
Cutaneous (CL)	<i>L. tropica</i> , <i>L. major</i> , <i>L. aethiopica</i> , <i>L. mexicana</i> , <i>L. braziliensis</i>		
Malaria	<i>Plasmodium</i>	8–10 days	Is not for acute infection!
	<i>P. falciparum</i> , <i>P. vivax</i> , <i>P. ovale</i> , <i>P. malariae</i>		Is mainly for patients with few parasites, retrospective confirmation of infection, and epidemiological surveys; antibodies persist for approx. 6 months after eradication of the parasite; species-specific diagnosis is normally not possible
Schistosomiasis			
Intestinal and/or	<i>Schistosoma</i> , <i>S. mansoni</i> , <i>S. japonicum</i> , <i>S. haematobium</i>	5–7 weeks	Is of great value during prepatent infection and in patients with a low egg load or neurological schistosomiasis; diagnosis is normally not species-specific; the prolonged and slow decrease of specific antibodies after treatment does not allow a post-therapeutical monitoring by serology
Urinary	<i>S. haematobium</i>	10–12 weeks	
Strongyloidiasis	<i>Strongyloides stercoralis</i>	17–28 days	Most test systems show considerable cross-reaction with other nematodes; IIFAT with filarial antigen is possible but not reliable for screening
Trypanosomiasis African	<i>Trypanosoma brucei</i>	3–21 days	Is not reliable during early infection but antibody concentration increases with prolonged infection; serodiagnosis of <i>T. b. gambiense</i> – infection is based on the detection of variant surface proteins, serodiagnosis of <i>T. b. rhodesiense</i> – infection of the invariant surface antigens; CATT, which is widely used under field conditions is not reliable for the detection of East African sleeping sickness
West African	<i>T. b. gambiense</i>		
East African	<i>T. b. rhodesiense</i>		
Toxocariasis	<i>Toxocara canis</i> <i>T. cati</i>	–	Is virtually the only possibility of detecting an infection; the rate of seropositivity in a population varies depending on the test system used (2–30 %)
Trichinellosis	<i>Trichinella spiralis</i>	5–28 days	IgM and IgG antibodies are undetectable or very low during acute infection when clinical symptoms occur; a diagnostic antibody level is reached 3–6 weeks after infection; in chronically infected individuals low level antibodies may persist for more than 20 years

After helminth infection, IgM antibodies may be constantly found.

Only few of the species-specific antibody detection systems (ELISA, WB) described in literature are available in routine practice. Cross-reaction between genus (helminths) and species (helminths, ► [protozoa](#)) is therefore a common phenomenon in the laboratory practice of today. This is of major importance for individuals living in or coming from regions where cross-reacting parasites are co-endemic (*Leishmania* spp. and ► *Trypanosoma cruzi*, *Babesia* spp. and ► *Plasmodium*, *Echinococcus* spp. and ► *Cysticercus*, filariae and other tissue ► [nematodes](#), *Schistosoma* spp.).

Serodiagnosis is currently most advanced for toxoplasmosis. There exists much knowledge on the diagnostic use of antibody classes during acute and congenital infection, standardization and quality control. Major advances were achieved in the serodiagnosis of ► [cestode infections](#). A routine serological differentiation between cystic and alveolar ► [echinococcosis](#) is possible by use of recombinant antigens. Human ► [cysticercosis](#) is specifically diagnosed by use of the WB. Although many propositions were published to improve the serodiagnosis in schistosomiasis by antibody detection to circulating antigens (CAA, CCA) more emphasis is put on the development of antigen detection in serum and urine of infected patients. This is also true for infection with ► *Wuchereria bancrofti*. ELISAs with E/S antigens have been shown to be specific and sensitive for antibody detection to *Toxocara* and *Trichinella*.

The IIFAT, once described as the most sensitive and specific assay for detection of infection with *Babesia* spp. in animals is now supplemented by specific and fast-to-perform ELISAs.

The serodiagnosis for tropical protozoal infections (amoebiasis, leishmaniasis, trypanosomiasis, malaria) has much profited from technical developments. User-friendly ELISAs are available for mass surveys, such as blood transfusion screening on malaria and Chagas' disease. Not only cross-reactions between *Trypanosoma*

cruzi, *T. rangeli*, and *Leishmania* spp. were overcome by using recombinant antigens but an increase in sensitivity for ► [cutaneous leishmaniasis](#) was also achieved, and prediction for active disease in ► [visceral leishmaniasis](#) and ► [amoebiasis](#) seems possible.

The interpretation of positive serological test results may be complicated by high background levels of seropositivity in areas endemic for a specific parasite. In patients with severe immunosuppression, serology is not a reliable diagnostic tool.

SERP

Serine-rich protein.

Serrasentis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of ► [Acanthocephala](#) found in fish (e.g., *S. sagittifer* in sea breams). Predator fish harbors the adult worms, while their late larvae (= post-cystacanths) are encapsulated in various species of fishes and preceding ones in arthropods. If humans ingest raw fish meat containing the larvae they may become infected, too.

Sex Determination

In protozoans direct evidence of sexual stages is limited to those species with known gametes (e.g., ► *gregarines*, ► *coccidia*, ► *Hypermastigida*), but remain scarce in other classes, although in some groups nowadays significant signs of sexuality are noted (e.g., in trypanosomes, gametes). Even in species that form gametes sex determination remains unclear because typical sex chromosomes are not present or not seen (since ► *chromosomes* do not become condensed). In metazoan parasites, however, there is significant genetic sex determination due to the formation and activity of sex chromosomes (heterosomes) in addition to autosomes. The most common system among animals is the XX/XY pattern. Except for a few groups (e.g., Sauropsida) in most animals the 2 X ► *chromosomes* were found in females (leading to homogametism), while in the male sex the XY situation occurs producing X or Y gametes (heterogametism). Therefore, it is not surprising

that in most parasites this XX/XY system occurs predominantly. However, in some parasitic genera (as well as in other animals) the Y chromosome is lacking (apparently lost during evolution). Then the males have one chromosome less than females and are thus characterized by a XO situation. This is for example the case in some ► [nematodes](#) (*Trichiuris trichiura*, ► [Strongyloides papillosus](#)), while closely related species (*S. ratti*, *T. ovis*) belong to the XY type. In ► [ticks](#) the events are even more complicated than in other groups. There is the XX/XO system (most Meta- and ► [Prostriata](#), except e.g., *Ixodes holocyclus*) as well as the XX/XY arrangement (all argasid ticks) and the occurrence of multiple sex chromosomes with apparently two different X chromosomes (e.g., ► [Amblyomma](#) spp.). A similar occurrence of multiple sex chromosomes is described in ► [Ascaris lumbricoides](#) and *A. suum*, where females possess 2 × 19 autosomes plus 2 sets of X₁, X₂, X₃, X₄, X₅, (=2 *n* = 48 chromosomes); while males have only one set of those X₁–X₅ chromosomes (=2 *n* = 43 chromosomes). In general X and Y chromosomes are different in shape and organization. However, in schistosomes the sex chromosomes of males and females are relatively similar. Thus they were described as ZZ in males and ZW in females. While Z is the largest chromosome of the 16 in ► [Schistosoma](#) spp., W belongs to the smallest ones in this genus. With respect to the formation of the gametes female schistosomes belong to the group of heterogametic animals.

Sex Steroid Hormones

General Information

In addition to sex-specific effects, sex steroid hormones also influence a variety of other functions like metabolism and immune response. It is therefore not astonishing that these hormones are also involved in parasite–host interactions and there is abundant evidence for gender-specific parasitic infection rates. But so far it is difficult to elucidate

Sex Steroid Hormones, Table 1 Sex differences in reaction to parasitic infections

Taxon	Higher susceptibility in hosts	
	Males	Females
Protozoa		
<i>Giardia lamblia</i>	+	
<i>Leishmania donovani</i>		+
<i>Leishmania major</i>	+	
<i>Leishmania tropica</i>		+
<i>Plasmodium chabaudi</i>	+	
<i>Toxoplasma gondii</i>		+
<i>Trichomonas vaginalis</i>		+
<i>Trypanosoma brucei</i>	+	
<i>Trypanosoma cruzi</i>	+	
Cestoda		
<i>Taenia crassiceps</i>		+

<i>Schistosoma mansoni</i> in mice		+
<i>Schistosoma mansoni</i> in men	+	
Nematoda		
<i>Heterakis spumosa</i>	+	
<i>Nippostrongylus</i> sp.	+	
<i>N. brasiliensis</i>	+	
<i>Strongyloides ratti</i>	+	

the underlying mechanisms for these interactions because of opposite effects in nearly related species (Table 1). Immunomodulatory effects alone are certainly not sufficient to explain all effects of the host’s sex steroid hormones on parasites since e.g., growth and ► [fecundity](#) are also affected. Whereas the effects of host hormones on parasites have often been investigated there is much less information available on the influence of the parasite on the host’s sex steroid hormones.

The structure of some steroid hormones are shown in Fig. 1. Lipophilic C18, C19, and C21 steroid hormones are synthesized *de novo* predominantly from cholesterol or cholesterylester and to a lesser extent from acetyl-CoA mainly in the gonads, but also in the cortex of the adrenal organ, and in the brain. The molecular weights of common steroid hormones are 277 (17β-estradiol), 288 (testosterone), 314 (progesterone), and 330 (dehydroepiandrosterone).

Sex Steroid Hormones,
Fig. 1 Sex steroid hormones: representative examples of female (17 β -estradiol and progesterone) and male (testosterone and dehydroepiandrosterone) steroid hormones

Physiological Function

During pregnancy there are pronounced changes in sex steroid hormone levels influencing immunity. Usually susceptibility to many infections including those by protozoan and helminthic parasites is increased as compared to non-pregnant females. For example, there is a higher infection rate with ► [malaria](#) parasites in pregnant females. Parasitaemia increases from the first to the second trimester. Primigravid females and their fetuses are at highest risk from malaria infection. Multigravid mothers show lower degrees of parasitaemia.

Pathology

One well-documented example of manipulation of the host's sex steroid hormone concentrations by a parasite is the effect of *Taenia crassiceps* on male mice. Infection with cysticerci reduces testosterone levels in the male to only 10 % of the control and simultaneously increases estradiol concentrations to 200 times their normal values.

Infected female mice also show an increase in estrogen blood levels and in uterus weight. This ► [feminization](#) by the parasite leads to a complete loss of sexual response of male mice towards females after 13 weeks of infection.

Implications

Dehydroepiandrosterone (DHEA) or its sulfate are potent agents protecting mice, rats, and Syrian golden hamsters from infection with the coccidian parasite ► [Cryptosporidium parvum](#), which leads to severe diarrhoeal diseases in animals and humans. Since it also protects mice from lethal infections with viruses and bacteria, there must be a general upregulation of the immune system by exogenous DHEA. In addition to this more general application of DHEA, there is also a specific one in *Schistosoma mansoni*-infected mice. In this case female mice are more susceptible to the infection than males. If during early infection DHEA is given, there is a partial protection against infection.

Sexual Dimorphism

Males and females of a species being morphologically clearly distinguishable.

Sexually Transmitted Infections

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This type of infections occurs in animals and humans. According to data published by the WHO, worldwide an estimated 240 million new cases of so-called curable infections such as chlamydia, gonorrhea, syphilis, and trichomoniasis occur every year among persons aged 15–49 years. Due to the fact that AIDS is a notifiable disease, it is noted that in several countries with high standards of medications the cases went down in the years between 1980s until end of 1990s, but since then increased again constantly. Basic data on trichomoniasis due to ► *Trichomonas vaginalis* do not exist, since cases are not notified in most countries.

Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Kiyoshi Shiga (Fig. 1) was a Japanese physician and bacteriologist. After studies on agents of epidemics in Kitasato's laboratory, he detected already in 1897 the agent of the bacterial dysentery (*Bacillus dysenteriae*) and developed 3 years later (1900) an antiserum against this disease. In the year 1901, he went as his famous colleagues Hata and Kitasato did to Germany and joined there the laboratory of Paul Ehrlich, where he stayed until 1903, when he went back to Kitasato's institute in Tokyo. Together with Paul Ehrlich, Kiyoshi Shiga developed the so-called trypan red as medicament against ► [African trypanosomiasis](#). Honoring his broad research, the former *Bacillus dysenteriae* was named *Shigella dysenteriae* and the toxin produced by this bacterium and others (e.g., EHEC) is now described as Shiga toxin. His relations to Germany were

always tight and thus he was elected as member of the historic Scientific Society Leopoldina (Leipzig).

Sickle Cell Anemia

Blood disease that is fatal in humans being homozygous carriers of the defect gene. On the other hand individuals being heterozygous for the gene responsible for sickle cell haemoglobin (HbS), in which a substitution of valine for glutamic acid occurs in the beta-chain of the molecule, are strongly (90 %) protected against severe Malaria tropica (due to *Plasmodium falciparum*). This effect is based on the fact that *P. falciparum* may not develop into mature schizonts after having entered the red blood cell due to the low oxygen tension and leakage of potassium from host cells during sequestration in capillaries, thus considerably reducing the pathologic effects, e.g., in the brain.

Sickle Cell Disease

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

In patients with sickle cell disease (endemic in sub-Saharan Africa and in regions of the Middle East) the hemoglobin (HbH) is altered to HbS by mutation, so that the β -globin at position 6 glutamate is replaced by valine. Therefore the heterozygous carrier (HbAS) has a tenfold lower risk to be killed by a malaria infection during childhood (Aidoo et al. 2002) and as a consequence the allele is maintained at a frequency of 5–30 % in respective malaria endemic regions. However, until today the molecular mechanisms of the protection

by the sickle cell hemoglobin (HbS) are still poorly understood (Cyrklaff et al. 2012). As hypothesis was established that hemoglobin S is unstable and open to oxidation of its iron from a ferrous (Fe^{2+}) to a ferric (Fe^{3+}) and subsequently to a ferryl (Fe^{4+}) station. Since oxidized hemoglobin potentially prevents host actin remodeling, which is done normally by *P. falciparum*-stages, the merozoites cannot develop to mature schizonts inside erythrocytes of persons with sickle cell disease. However, the disease is fatal for homozygous carriers of the defect gene.

Sickle Cell Disease: Treatment Trials

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Traditional treatments of sickle cell disease (SCD) were based on fluid replacement and ingestion of opioid analgesics for acute and/or chronic pain brought only relief of symptoms, but no change in the basic pathophysiology. The only available pathophysiological treatment today is the application of hydroxyurea (hydroxycarbamide). This compound leads to the increase of the HbF (fetal hemoglobin) concentration. But this substance is cytotoxic with numerous side effects; however, it prolongs the life of SCD patients especially if constantly blood transfusions occur. In children

some success was achieved by hematopoietic stem cell transplantation.

Simond, Paul-Louis (1858–1947)

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The French scientist Paul-Louis Simond – member of the famous ► [Pasteur](#)

Institute at Paris – came into contact with the plague disease, which had threatened and killed as “Black death” during centuries millions of humans, 3 years after Yersin and Kitasato had discovered in 1894 – both working simultaneously in Hong Kong – the plague bacillus. He was sent to Bombay (India) as successor of Yersin in order to bring an experimental serum into use that had been developed by Yersin at the Pasteur Institute. At this time, the transmission of plague was under intense discussion in the German, English, Russian, Italian, and French scientific communities, and the idea of an activity of arthropods as vectors of pathogens was in its “children’s shoes” or even not yet born. Simond, as an active physician, noted that at the beginning of a plague infection, small blisters occurred at the skin, containing a fluid with numerous bacilli. He concluded that this blister (phlyctène précoce) should be the infection site, which later becomes the large necrotic boubon (French: charbon pesteux). Simond had the idea that at the beginning this small blister could be due to an insect bite. He studied cockroaches first and rather soon fleas, which were abundant there due to the occurrence of masses of rats in the poor quarters of this overcrowded Indian town. He detected the bacilli inside the fleas which he collected from dead rats. At the same time, Kitasato’s colleague Ogata described in 1897 similar findings in fleas in German language in a German scientific journal, but he missed to draw Simond’s conclusions that fleas are the plague vectors and that therefore rats as hosts of fleas should be kept away from human surroundings. Simond depicted his findings and conclusions in a protocol in the year 1898, informed thereby the director ► [Roux](#) of the Pasteur Institute at Paris, who published the data in the “Pasteur Annales,” so that this idea was spread among scientists without being officially published by Simond in a scientific journal at this early time. However, as it is usual, revolving ideas are hit by skepticism – not only by the home-proud English scientific scene but also by French colleagues. This offense against a flea

transmission of plague was kept alive, although there had been several scientific hints on the possible vectorship of arthropods before Simond’s observations (e.g., ► [Finlay](#) 1864 discussed mosquitoes as vectors of diseases of – at this time still unknown – viruses of the yellow fever, ► [Manson](#) saw in 1878 relations between mosquitoes and transmission of filarial worms, as well as ► [Bruce](#) in 1884 described the involvement of tsetse flies in the transmission of trypanosomiasis). However, after many troubles and after an official publication of Simond in French in the year 1905, two English scientists confirmed finally the vectorship of fleas in the transmission of the plague bacterium that is now called *Yersinia pestis* (Bacot and Martin [1914](#)).

Simondsia

Genus of a nematode family in pigs. Intermediate hosts are beetles and cockroaches.

Simuliidae

From Latin: *simulare* = to make similar.
► [Blackflies](#), ► [Diptera](#).

Simuliidosis

Disease due to bites of simuliids, see [Table 1](#).

Simuliidosis, Table 1 Simuliids and control measurements

Parasite	Host	Vector for	Symptoms	Country	Therapy		
					Products	Application	Compounds
<i>Simulium</i> spp. (blackflies)	All animals, Man	<i>Onchocerca volvulus</i> (human filariasis)	Edema, allergic reactions (simulio-toxicosis)	Worldwide	1 % Vapona insecticide (Durvet)	Spray	Diclorvos
<i>Simulium reptans</i>	Ruminants, Horse, Pig		Edema, allergic reactions (simulio-toxicosis)	Central-Northern Germany, Austria, foothills of the Alps			
<i>Odagmia ornata</i>	Ruminants, Horse, Pig	<i>Onchocerca gutturosa</i>		Worldwide			
<i>Wilhelmia equina</i>	Ruminants, Horse, Pig			Switzerland, Germany			
<i>Boophthora erythrocephala</i>	Ruminants, Horse, Pig			Germany, Switzerland, Poland, Czechoslovakia, Italy, France			

Simuliotoxicosis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Shock reaction of cattle or other animals due to injection of large amounts of saliva of numerous black flies (► *Simulium* species) at the same time.

Simulium

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Latin: *simulare* = betraying, cheating.

Classification

Genus of the dipteran mosquito family Simuliidae.

Life Cycle

The species of the genus *Simulium* contain rather small (2–6 mm) specimens, which look dark and

Simulium, Fig. 1 LM of an adult stage

thus are called “blackflies” (Fig. 1). Since their thorax segments are dorsally protruded, they also got the name “buffalo flies.” There are nearly 1,800 species described in 19 genera, 4 of which have zoonotic importance (*Simulium*, *Prosimulium*, *Austrosimulium*, *Cnephia*). *Simulium*, *Odagmia*, *Boophthora*, and *Wilhelmia* have importance for humans, too. The stages of the life cycle, which occurs in quickly running rivers, is shown in Fig. 2 (p. 1309). Only the females suck blood and thus may transmit pathogens (e.g., ► *Onchocerca*). The females live for 3 months, while eggs and larvae overwinter (in Europe). The symptoms of simuliotoxicosis (due to injection of saliva during bites) are necrosis, edema, severe itching until death. The adult simuliids may fly up to 10 km per day, but mostly do not enter stables. They bite at daylight and are feared by cattle, if the bloodsuckers attack en masse (Fig. 3, p. 1309). ► *Diptera*, ► *Insects*, Fig. 9D, ► *Filariidae*, ► *Leucocytozoon simondi* (Figs. 4 and 5).

Simulium ochraceum

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This species is the main vector of ► *Onchocerca volvulus* worms in Latin American countries.

Simulium: Subgenera

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

There is a worldwide distributed spectrum of subgenera, within which nearly 1,600 species are described. The most widespread genera are *Simulium* (1,203 species), *Prosimulium* (110 species), *Nevermannia* (169 species), *Gigantodax* (65 species), *Austrosimulium* (25 species), *Eusimulium* (33 species), *Psilopelmia* (50 species), and *Cnephia* (10 species).

Skin Dimmer

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Trivial name for ► [Chilodonella](#) species of fish.

Skin Diseases, Animals

General Information

Parasitic diseases of the skin are of major economic importance. Discomfort and pruritis interfere with the normal rest and feeding of the

animal, and the loss of protective function of the skin facilitates bacterial infection. In addition, the commercial value of the hides is often reduced. Some ectoparasites, such as bloodsucking flies and some species of ► [ticks](#) are of great economic importance because of the diseases they transmit. However, the skin lesions produced by these parasites are of relatively minor significance. Finally, parasitic infections of the skin and the sometimes ugly lesions they cause affect the general appearance of the animal, and upset the owner. It is intended to deal only with those parasites which are of importance owing to the damage they cause to the skin (Table 1). Most of these are arthropods. However, some ► [protozoa](#) and helminths may occasionally be responsible for localized skin lesions and these will be referred to briefly.

Protozoa

Cutaneous lesions occur in several systemic protozoal infections, including ► [besnoitiosis](#) in cattle and horses, ► [dourine](#) (*Trypanosoma equiperdum*) in horses and leishmaniasis in the dog.

Cattle – and rarely horses – serve as intermediate hosts of ► [Besnoitia besnoiti](#). In cattle, the parasite mainly infects cells of the connective tissue and produces characteristic cysts with a very thick wall. Clinical besnoitiosis in cattle is characterized by two sequential stages: an acute febrile stage and a chronic seborrheic stage. Persistent high fever is the first clinical sign. During the febrile stage cattle may develop a photophobia, anasarca, ► [diarrhoea](#), and swelling of the lymph nodes. This is followed by a progressive thickening and wrinkling of the skin and the development of a marked ► [alopecia](#). During the seborrheic stages denuded parts are covered by a thick scurfy layer. In chronic cases the skin remains alopecic, lichenified, and scaly. The cysts may be visible macroscopically in the scleral conjunctiva or nasal mucosa as small, round, white foci. Death may occur in severe cases.

► [Trypanosoma equiperdum](#) causes typical oedematous swelling of the external genitalia and ventral abdomen in horses. Raised urticarial

Localization: 1 Generalized/not specific, 2 Head, neck, 3 Limbs, 4 Thorax, ventral abdomen, 5 Back, hindquarters

plaques, 4–5 cm in diameter, called silver dollar plaques, may also appear, especially on the flanks.

The cutaneous lesions of leishmaniasis commonly observed in dogs include a dry exfoliative dermatitis, ulcerations, a periorbital alopecia, diffuse alopecia, and onychogryphosis.

Helminths

The skin is the natural site of entry for a number of parasites that have their final habitat in the gastrointestinal tract or elsewhere, e.g., the ► [nematodes](#) ► *Strongyloides*, *Ancylostoma*, ► *Bunostomum*, and *Gnathostoma*, and the trematode ► *Schistosoma*. The passage of these parasites rarely causes cutaneous lesions in animals, except for *Ancylostoma*. Hookworm dermatitis begins with the appearance of red papules on those parts of the body which are often in contact with the ground; later these areas become uniformly erythematous, and then thickened and alopecic. Pruritis is mild but evident, especially during initial larval penetration. Repeated hookworm penetration of the foot in dogs may result in secondary bacterial invasion producing gross enlargement of the feet and paronychia. As a result of the paronychia the claws may become deformed.

The ► [helminth](#) infestations that remain more or less localized to the dermis are the filariid parasites most commonly seen in cattle, sheep and horses (Onchocercosis, Animals, ► [Stephanofilariosis](#), ► [Elaeophoriosis](#), Elaeophorosis, Parafilariasis, Parafilariosis, ► [Habronemiasis](#), Habronemosis). Some filariid worms have been reported to occasionally cause cutaneous lesions, e.g., *Dirofilaria* (Dirofilariosis, Man), ► [Brugia](#), ► [Dipetalonema](#).

Arthropods

Mite Infestation

Several ► [mites](#) infest animals and cause significant dermatological diseases. The lesions are the result of mechanical damage to the skin and

probably also of hypersensitivity reactions to toxic secretions (Acariosis, Animals).

Tick Infestation

Ticks, like the other mites, are important arachnid parasites of both large and small animals. They play a major role as vectors of a large number of diseases. Ticks also harm their hosts more directly by causing local injury at the site of attachment. Ticks suck blood and heavy infestations may cause ► [anaemia](#). Sites of tick bites attract flies and may become the site of development of myiasis.

Lice Infestation

Several species of ► [lice](#) infest large and small animals. Domestic animals may suffer from infestations with both biting (► [Mallophaga](#)) and sucking (► [Anoplura](#)) lice. Lice are extremely host-specific. Infection is a seasonal problem and the signs associated with pediculosis are extremely variable. Most lesions result from skin irritation and ► [pruritus](#). They include alopecia alone, papulocrustous dermatitis, and damage to wool or hide caused by rubbing or biting. Sucking lice may induce anaemia. Constant irritation during lice infestations causes a loss of weight and a decrease in milk production.

Flea Infestation

► [Fleas](#) are the most common ectoparasites of dogs and cats. The clinical manifestations are highly variable. Some animals remain asymptomatic carriers, others develop a flea-bite dermatitis which is a reaction to irritant substances in the flea's saliva. The infection may also cause a mild papulocrustous dermatitis with a mild pruritis. An acute flea-bite allergic dermatitis may develop in dogs, causing intense pruritus and erythema. Secondary lesions which result from self-excoriation include breaking of hair and local alopecia, and occasional areas of acute dermatitis. Fleas may also induce anaemia in heavily infested animals (see Table 1).

Flying and Biting Insect (Diptera) Infestation

Flying and biting insects are ubiquitous pests for domestic animals. Not only do they cause a loss of

productivity by continuously annoying the animals, they may also cause diseases. Direct or indirect pathological effects of these flies include the deposition of larvae on or into the skin (myiasis), the local irritation (► [Dermatitis](#)), the injection of antigens inducing hypersensitivity reactions, the blood-feeding activities leading to anaemia; and the inoculation of pathogenic organisms.

The most important flies are those species whose larvae are highly destructive, facultative or obligate parasites. Infestation with such larvae is called myiasis. Warbles, caused by ► [Hypoderma bovis](#) and *H. lineatus* occur chiefly in cattle. They form on the back of the animal multiple ► [nodules](#) with breathing pores which may be painful upon palpation. Affected animals may manifest signs referable to the migration path of the individual grub prior to the development of nodules. Economic losses are due to gadding, milk and meat loss, and depreciation of the carcass and hide. Destruction of ► [Hypoderma](#) larvae in the infected host may cause severe clinical reactions, which are sometimes fatal. These toxic manifestations appear in the form of local and systemic effects which include, in the instance of *H. bovis*, inflammatory lesions in the spinal canal accompanied by stiffens, and ataxia, paraplegia, and collapse. *H. lineatum* larvae cause inflammation in the oesophageal wall, dysphagia, drooling of saliva, and bloating. Shocklike cardiorespiratory signs may accompany any of these conditions. The exact nature of these adverse signs is not known but it seems possible that, in the living host, adverse reactions to dying larvae may comprise both direct (toxemic) and indirect (► [Anaphylactic Shock](#)) components.

Myiasis caused by screwworms has been a cause of great financial loss in the livestock industry. There are two important species of “screw-flies”: ► [Callitroga \(Cochliomyia\) hominivorax](#) and ► [Chrysomya bezziana](#). These flies are obligatory parasites which may infect all domestic animals, and which only lay eggs on fresh wounds. The infection causes intermittent irritation and pyrexia. A cavernous lesion is formed, characterized by progressive liquifactive necrosis and haemorrhage that oozes a foul-smelling liquid.

A gross fibrous involution follows the larval exodus. Significant haematological and biochemical changes include an initial neutrophilia, anaemia, and decreased total serum protein with a progressive rise in serum globulins. A significant loss in body weight occurs in infested animals.

Cutaneous infestation by blowfly maggots causes heavy mortality in sheep and significant losses in wool production in many countries. A large number of species belonging to the genera *Lucilia*, *Calliphora*, *Phormia*, and *Chrysomya* are capable of causing the disease. Moisture and warmth are essential for the hatching of eggs and the development of the larvae. The breech is by far the most common site involved because of soiling and excoriation by the soft faeces and the urine of the animal. The affected sheep are restless, do not feed, tend to bite or lick at the “struck” area. Examination shows a patch of discoloured, greyish-brown, moist wool with an evil odour. In very early cases the maggots may be found in the wool attached to the skin, while in the latter stages the maggots burrow into the tissues causing an inflamed wound which produces a foul-smelling liquid. There may be fever, and death may follow.

The larvae of the Tumbu-fly *Cordylobia anthropophaga* penetrate the skin of dogs, cats, and humans in sub-Saharan Africa and produce painful boil-like swellings.

The housefly (*Musca domestica*), ► [stable fly](#) (*Stomoxys calcitrans*), face fly (*M. autumnalis*) and the hornfly (*Haematobia irritans*) are responsible for considerable annoyance of animals. Wheals, crusts, and cutaneous papules and nodules have mainly been associated with the biting flies ► [Stomoxys](#) and *Haematobia* and several tabanid species.

Mosquitos (family Culicidae) considerably annoy man and animals if present in large numbers. Individuals may respond more or less sensitive to mosquito bites by local swelling at the site of mosquito bite. Certain species of mosquitos are important vectors of pathogens (e.g., heartworm, blue tongue disease, malaria).

► [Culicoides](#) spp. are small midges which inflict extremely painful bites. In horses they are associated with hypersensitivity reactions leading to a pruritic dermatitis (referred to as sweet ► [itch](#)

or summer dermatitis). Pruritus is most intense along the base of the mane and tail and on the withers. However, the condition can also involve other parts of the body. Lesions consist of self-inflicting hair loss, excoriations with crusting and scaling, and – after a period of incessant rubbing – striking hyperkeratosis and thickening of the skin.

The saliva of blackflies (family Simuliidae) contains a toxin (simuliotoxin) that induces anaphylactic-responses when injected into the site of biting. The response can be localized or develop into a generalized acute anaphylactic shock syndrome with rapid death. Oedematous swelling of the throat may lead to suffocation. Due to their breeding habits blackflies usually occur in the vicinity of oxygen-rich bodies of flowing water and occur in large numbers mainly in spring.

Treatment

► **Arthropodicidal Drugs**, Ectoparasitocidal Drugs.

Skin-Snips

Method of diagnosis in onchocercosis (► **Filariidae**).

Skrjabinagia

Genus of nematodes introducing an ostertagiosis in cattle. ► **Alimentary System Diseases**, **Ruminants**.

Skrjabinema

Genus of the nematode family Oxyurida. For example *S. ovis* is found worldwide in the colon of goats and sheep (male 4 mm, female 8 mm).

Prepatent Period

30–45 days. The 60 × 30 µm-sized eggs already contain the infectious larva 3.

Symptoms of Disease

Itching along the anal groove.

Therapy

Nematocidal Drugs.

Skrjabinigylus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Genus of metastrongylid nematodes parasitizing in the nasal and frontal cavities of their hosts. Six species are described in the Northern Hemisphere.

- *S. chitwodoorum*
- *S. lutrae*
- *S. nasicola*
- *S. petrowi*
- *S. rylikovi*
- *S. santaceciliae*

The adult worms of these species range in the same size, which is given for *S. petrowi* in martens (e.g., *Martes martes*), where females reach a length of 28–39 mm and males 11–16 mm with a body width of about 0.5 mm (♂), respectively, up to 1 mm (♀).

Sleeping Sickness

Synonym

African Trypanosomiasis

Pathology

The African trypanosomes are parasites of humans and domestic animals causing the disease African trypanosomiasis (Trypanosomiasis, Animals, Trypanosomiasis, Man) or sleeping sickness. *T. brucei gambiense* infection occurs in Central and West Africa and is slowly progressive, and generalized. Initially the trypanosomes are present extracellularly in the subcutaneous tissue at the site of the bite of the tsetse fly and give rise to a papular and later ulcerating lesion, often called a ► [chancres](#), which persists for about 2 weeks. In the second stage trypanosomes enter the bloodstream and multiply there. In the third stage there is fever and lymphoid ► [hyperplasia](#) leading to enlargement of the spleen and especially of the cervical lymph nodes, which contain trypanosomes useful for diagnosis by puncture and smear. The fourth stage is central nervous invasion associated with intermittent fever. Trypanosomes in the neuropil and the cerebrospinal fluid produce diffuse meningoencephalitis with lymphocytes, plasma cells, and histiocytes infiltrating mainly the gray matter, the Virchow-Robin perivascular spaces, and the vessel walls. Notable are the plasma cells with multiple eosinophilic proteinaceous globules, or morula cells, found in the meninges. Trypanosomes are not easily found but can be cultured from the spinal fluid. Neuronal loss and demyelination are not prominent, but the cortical microglial and astrocytic gliosis is impressive, especially in the superficial cortex. This inflammatory reaction extends to the spinal ganglia and cranial and spinal nerve roots. These central nervous system lesions are accompanied by headache, apathy, wasting of musculature, emaciation, tremors, inability to walk, and eventually to somnolence, paralysis, coma, and death, usually after a course of 1–3 years. Often the

disease is complicated by other infections such as ► [malaria](#), schistosomiasis, animals, schistosomiasis, man, ► [hookworm disease](#), or ► [pneumonia](#). Hematologically there is anemia and granulocytopenia, sometimes with lymphocytosis and hyperglobulinemia, especially of IgM.

Immune Responses

These kinetoplastid ► [protozoa](#) live only extracellular and have evolved remarkable ► [immune evasion](#) mechanisms. Since *T. brucei* infects laboratory rodents readily, the mouse model has been used for almost all immunological studies. Different inbred strains of mice exhibit different resistance to *T. brucei*, but all eventually succumb to the parasite. As in other experimental parasitic diseases resistance is under polygenic control, but the exact nature of the genes involved is not known. The initial host response toward *T. brucei* is characterized by the early release of inflammatory mediators associated with a type 1 immune response. It has been shown that this inflammatory response is dependent on activation of the innate immune system mediated by the TLR-adaptor molecule MyD88. MyD88-deficient macrophages are nonresponsive toward the variant-specific surface glycoprotein (VSG). Infection of MyD88-deficient mice with *T. brucei* resulted in elevated levels of parasitemia. Analysis of several TLR-deficient mice revealed a partial requirement for TLR9 in the generation of an efficient Th1 response. These results implicate the mammalian TLR family and MyD88 signaling in the innate immune recognition of *T. brucei*.

B Cells, Antibodies, and Antigenic Variation

The metacyclic and bloodstream forms of *T. brucei* are uniformly coated with the ► [variant surface glycoprotein](#) (VSG). This GPI-anchored protein has a highly polymorphic N-terminus

forming the exposed domain. Up to 1,000 different VSG genes distributed throughout the genome are present in the genome of the parasite. At any one time, only a single VSG gene is actively transcribed at a telomeric expression site. The switching from one VSG variant to another by translocation events or telomeric *in situ* activation occurs in a spontaneous manner at a surprisingly high rate of 10^{-4} to 10^{-5} per cell division. ► **Antigenic variation** leads to the characteristic fluctuating parasitemia, as successive VSG variants elicit an antibody response and are then destroyed. The primary antibody response is a T cell-independent IgM response, but T cell-dependent IgG responses against normally buried nonvariant VSG epitopes can be also initiated after phagocytosis of trypanosomes.

Immunosuppression

Immunosuppression, which occurs both in infected animals and humans, has been extensively studied in the mouse model of trypanosomiasis. Lymph node enlargement and splenomegaly are accompanied by massive accumulation of B cells and null cells. The massive polyclonal B cell activation manifests in elevated IgM levels and autoantibody production. The alterations in the cellularity and architecture of the lymphoid system are accompanied by a dramatic suppression of T and B cell responses to antigens and mitogens. These effects are mediated by intermediate cells, in particular suppressor macrophages. The transfer of as few as 40,000 peritoneal or splenic macrophages from trypanosome-infected donor mice were capable of causing a 50 % suppression of recipient mitogen responses. The suppressor macrophages display an activated phenotype and especially two secreted products of these cells, PGE2 and NO, have been shown to mediate suppressive effects. Both, inhibitors of iNOS (L-NMMA and L-NAME) and cyclooxygenases (indomethacin) led to a partial abrogation of suppressor macrophage activity, and when used in combination there was a complete restoration of proliferative

responses in splenocyte cultures from *T. brucei*-infected mice. The role of NO during murine trypanosomiasis has also been studied *in vivo*. Treatment of infected mice with L-NMMA resulted in a restoration of mitogen-driven T cell proliferation in the spleen and surprisingly also in a significant reduction of the first parasitemic peak. In contrast to other parasites, NO does not significantly affect trypanosome proliferation. While *T. brucei* is killed by NO *in vitro*, the presence of red blood cells, as in the natural habitat of the parasite, the bloodstream, abolishes this effect completely. This is a result of hemoglobin acting as high affinity sink for Nitric Oxide (NO).

While the suppressor macrophage products PGE2 and NO are clearly damaging to the host, TNF has a more ambiguous role. TNF has been originally identified as the cachexia-inducing factor in chronic trypanosomiasis. However, treatment of primed mice with anti-TNF antibodies reduced the duration of survival, and subsequent studies showed a direct trypanolytic activity of TNF.

T Cells

Given the central role of activated macrophages in African trypanosomiasis, IFN- γ which has been found to be significantly upregulated in infected humans and mice most likely plays a central role. Recent studies have shown three independent cellular sources of IFN- γ in experimental trypanosomiasis. First, VSG-specific MHC class II restricted CD4⁺ Th1 cells have been identified. A second source is a CD8⁺ T cell population which is directly activated by a 42–45 kDa trypanosomal protein designated trypanosome-derived lymphocyte triggering factor (TLTF). A third source for IFN- γ early after *T. brucei* infection (e.g., days 2–4 of infection) are NK cells, as revealed by (1) a significant T-cell-independent production of IFN- γ in infected nude mice and (2) the reduction of IFN- γ production after depleting NK cells with anti-asialo-GM antibodies. A contribution of NK cells to the

pathogenesis in murine trypanosomiasis is further suggested by the finding that NK cell-deficient beige mice showed prolonged survival time after *T. brucei* infection. Most interestingly and in addition to its role in the generation of activated suppressor macrophages IFN- γ appears to have also a direct stimulatory effect on the growth of the parasite. The proliferative response of *T. brucei* to IFN- γ has been demonstrated in axenic cultures. In line with the parasite growth-promoting activity of IFN- γ parasitemia in IFN- γ -deficient mice were consistently lower than in Wild-type mice. In contrast, IFN- γ receptor $-/-$ mice displayed a more rapid parasitemia and shorter survival time, ascribed to higher levels of free plasma IFN- γ in these mice. Thus, IFN- γ represents another host cytokine in addition to epidermal growth factor described earlier which is able to directly influence the growth of *T. brucei*.

In addition to IFN- γ there appear to be factor (s) produced by the parasite acting as costimulators for macrophage activation. This activity was named trypanosomal macrophage-activating factor (TMAF) and although there is currently no information on the molecular nature of TMAF it appears to be distinct from VSGs of *T. brucei*. However, since TMAF was able to induce both PGE2 and NO synthesis by host macrophages, it may represent a virulence factor of the parasite contributing to the immunosuppression observed in trypanosomiasis.

Main clinical symptoms: Fever, local ► edema, possibly polyadenitis, neural complications, death.

Incubation period: local oedema: 1–21 days, fever: 3 weeks; cerebral disorders: 3 months in *T. b. rhodesiense*, 9–12 months in *T. b. gambiense*.

Prepatent period: 1–3 weeks.

Patent period: Years in chronic cases.

Diagnosis: Microscopic determination of blood stages serologic methods.

Prophylaxis: Avoid bite of tsetse flies in endemic regions.

Therapy: Treatment see Trypanocidal Drugs, Animals, Trypanocidal Drugs, Man.

**Sleeping Sickness:
Humans – Symptoms**

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Infection with both *Trypanosoma brucei gambiense* and *T. b. rhodesiense* lead to diseases called sleeping sickness and/or trypanosomiasis. Although the agents of this disease are subspecies of the same *Trypanosoma brucei* species, they differ in many general aspects (Table 1) and in their introduced clinical symptoms which can be grouped into two successive phases:

- 1. Hemolymphatic phase
- 2. Meningoencephalitic phase (Table 2)

Sleeping Sickness: Humans – Symptoms, Table 1 Basic differences between *Trypanosoma brucei gambiense* and *T. b. rhodesiense* and their pathogenic effects

Criteria	<i>T. b. gambiense</i>	<i>T. b. rhodesiense</i>
Distribution	West and Central Africa	Southeast Africa
Hosts	Main hosts: humans	Main hosts: ruminants
	Reservoir hosts: pigs	Accidental hosts: humans
Vectors	Tsetse flies of the <i>Glossina palpalis</i> group	Tsetse flies of the <i>Glossina morsitans</i> group
Climatic distribution	Humid biotopes	Dry grasslands
Virulence	Moderate to very variable	High
Parasitemia	Low, intermittent	Often high, persistent
Clinical progress	Chronically	Acute
Clinical symptoms	Months up to 6 years	Weeks, rarely several months
Main damage	Central nerve system	Heart
Final lethal symptoms	Chronic meningoencephalitis	Myocarditis, pancarditis, polyserositis

Sleeping Sickness: Humans – Symptoms,
Table 2 Common symptoms of trypanosomiasis during the two main consecutive phases 1 and 2

1. Hemolymphatic phase	2. Meningoencephalitic phase
Skin ulcer (chancre)	Sleep disturbances
Fever, headache	Psychic problems, disorientation
Pruritus, exanthemas, edemas, ascites	Motility problems, bad reflexes
Hepato-, splenomegalias	Tonus disturbances: rigor, hypotonia
Muscle and bone pain, cardiac problems	Tremor, paresthesias, ataxia, loss of coordination
Endocrinal disturbances, proteinuria	Neurological symptoms: cramps, loss of reflexes, loss of consciousness, coma, death

Slender Forms

Stages of the *Trypanosoma brucei*-group, which divide in the host's blood, while the stumpy forms are prepared for a life in the vector. Polymorphism.

Slowing-Down Phenomenon

Several parasites (e.g., *Echinococcus* cysts, ► *Ribieroria* ► *trematodes*) lead to deformities in their intermediate hosts and thus decrease the hosts' ability to flee from a predator (= final host).

S-Methoprene

Chemical Class

Juvenile hormone agonist (juvenile hormone analogue).

Mode of Action

Insect growth regulator (IGR, juvenile hormone mimics). ► [Ectoparasitocides: Inhibitors of Arthropod Development](#).

Sm-Genes

Schistosomal (*S. mansoni*) gene products sm 1, sm 14, sm 23, sm 26, sm 28, sm 62 (similar ones exist in *S. japonicum*) are candidates used for the development of vaccines. ► [Vaccination](#).

Smith, Theobald (1859–1934)

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Born in Albany (New York) as son of German immigrants he studied medicine. Due to his knowledge of the German and French language, he was able to read the papers of Pasteur (Paris) and Koch (Berlin), which stimulated him. He was one of the most important investigators of the Texas cattle fever (see ► *Babesia* species). Together with his colleague Kilbourne and Curtice he proved that ticks are vectors of this disease, which killed hundred thousands of cattle at that time in the USA, while Robert Koch and

much later Schein, Friedhoff and Mehlhorn demonstrated the full life cycle of these parasites in the ticks. Smith is also considered to be the discoverer of the agents of the disease due to *Salmonella enterica*. In 1895 he obtained a Professorship at Harvard University and later (1915) at Princeton. Famous is his monography of the Texas fever, which appeared in the year 1893. He died in 1934 in New York.

Snipe Flies

Common name for the fly family Rhagionidae with the genera *Atherix* (South and North America), *Austroleptis* and *Spaniopsis* (in Australia) (► [Spaniopsis](#), Fig. 1), and *Symphoromyia* (in Europe, Asia, and North America). They land noiselessly on human skin, bite very painfully, and often occur en masse.

Snoring Disease

Disease due to infection of cattle with the trematode *Schistosoma nasale* (► [Respiratory System Diseases, Ruminants](#)).

Snow Flake Opacities

Symptom of onchocercosis in the eye (occurs due to dead microfilariae).

Soboleviacanthus

Genus of tapeworms of birds. *S. gracilis* (syn. *Hymenolepis gracilis*) is found in European chicken, *S. columbae* in doves.

SODs

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes metalloenzymes which catalyze dismutation of O_2^- to H_2O_2 . SODs in trypanosomatid parasites are exclusively dependent on iron for their activity, while mammals contain Cu/Zn- and Mn-dependent SODs in the mitochondrial matrix and in cytoplasm. *Leishmania* species have in total three functionally characterized FeSODs. Two isoforms of them have been localized in the glycosomes, which contain enzymes involved in the glycolytic pathway.

Sparganosis

Bin Ye

Department of Parasitology, Chongqing Medical University, Chongqing, China

Sparganosis is an infection of ► *sparganum*, a ► *plerocercoid* larva of the genus *Spirometra* tapeworm.

The first sparganosis case was described by ► *Patick Manson* in China in 1882. The disease is most prevalent in Asia, especially in China, Vietnam, Thailand, Korea, and Japan, although cases have been described sporadically around the world. Most cases in Asian countries are caused by *Spirometra mansoni*, while most cases in North America by ► *Spirometra mansonioides*.

Usually, dogs and cats are the definitive hosts of Pseudophyllidea tapeworm *Spirometra* spp. ► *Sparganum* is a parasite of carnivores, found usually in amphibians (second intermediate hosts) or reptiles (paratenic hosts). As an accidental host, human becomes infected by consuming raw tadpoles or raw flesh of amphibians (Fig. 1), reptiles, birds, or mammals such as pigs and dogs for medicinal purposes or for indigenous food cultures or by placing raw flesh poultices of amphibians or snakes infected with spargana on open wounds, lesions, and eyes for medicinal

reasons, even by drinking contaminated water containing copepods (Fig. 2) infected with ► *pro-cercoid* larvae of *Spirometra*.

Sparganosis, Fig. 2 The copepod infected with *Spirometra* pro-cercoids may serve as the first intermediate host of *Spirometra*

Sparganosis, Fig. 1 A *sparganum* dissociated from the frog's thigh flesh

The incubation period of sparganosis resulting from the application of raw flesh poultices is 2 days to 10 days; however, it is described that sparganum larva can remain in the body for months or years before symptoms present (Liu 1990). The spargana can cause migratory inflammation nodules or abscesses in the human body. The larva in the abscess is surrounded by an intense mixed inflammatory reaction, often containing large numbers of eosinophils. The nodule is delimited by granulation tissue. By lesion locations, sparganosis is divided into subcutaneous, ocular, buccal cavity, cerebral, and visceral types. Clinical symptoms also vary according to the locations of spargana. Most commonly, the spargana invade and migrate through subcutaneous tissue or muscle, especially in the abdominal wall, chest, limbs, breast, groin, labia, or scrotum. The early stages of disease are often asymptomatic. The larvae may cause small and migratory subcutaneous nodules (1 to 2 cm in diameter) with erythema, pruritus, and swelling and are often accompanied by painful edema. Discrete subcutaneous nodules may appear and disappear over a period of time. The ocular and maxillofacial sparganosis is found occasionally. The symptoms of the ocular sparganosis include eye pain, edematous swelling, lacrimation, orbital cellulitis, exophthalmos, and corneal ulcer. If untreated, a mass ocular lesion may lead to blindness. Although the cerebral or visceral case is rare, the brain abscesses might be serious. Seizures, hemiparesis, and headaches are common symptoms of cerebral sparganosis.

Preoperative diagnosis is rare, although the infection may also be diagnosed by identification of eosinophilia or identification of sparganum in a tissue specimen. Diagnosis depends on pathological examination of sparganum sections after tissue biopsy and excision of nodule lesion. The lesions in the brain can be observed by tomography and magnetic resonance imaging. Antisparganum ELISA test of cerebrospinal fluid or serum may be used when biopsy and excision procedures are not feasible. Seroprevalence of IgG antibodies for spargana in sera of patients can be measured by ELISA; it should be included in differential diagnosis for patients with

eosinophilia-associated lesions of the central nervous system, liver, and lungs (Lee et al. 2010). ELISA using excretory-secretory antigens of *S. mansoni* spargana may be applied to early serodiagnosis of sparganosis since its specificity in detecting serum samples of patients with cysticercosis, echinococcosis, paragonimiasis, clonorchiasis, and schistosomiasis and healthy persons was significantly greater than that of crude antigen ELISA (Cui et al. 2011). Two-dimensional electrophoresis followed by immunoblot analysis might be highly available in differential serodiagnosis of human sparganosis because the 31 kDa and 36 kDa proteins of the sparganum could invoke specific and sensitive antibody responses, and the sera from sparganosis patients recognized 8–10 protein spots of 31 and 36 kDa with different isoelectric point (pI) values with variable combinations, in which four spots of 31 kDa with pIs 3.4, 3.9, 4.0, and 4.1 and one 36 kDa spot (pI 3.5) appeared to be specifically reactive (Rahman et al. 2011).

Surgical removal is the best choice for therapy of sparganosis. The antihelminthic praziquantel or ► [albendazole](#) is often used for viscera sparganosis. However, it was demonstrated that albendazole had no obvious efficacy for treating sparganosis in mice (Cui et al. 2012) and that albendazole at a dosage of 400 mg bi-daily for 30 days was ineffective to human cerebral sparganosis (Gonzenbach et al. 2013). The treatment with praziquantel has produced only limited success when the chemical was administered at a total dose of 120–150 mg/kg body weight, over a 2-day period. A successful therapy for cerebral sparganosis may be achieved by a high-dosage regimen of praziquantel (3 × 25 mg/kg body weight daily) for 7 days combined with cimetidine (3 × 400 mg daily) and a high carbohydrate diet to increase plasma level of praziquantel (Gonzenbach et al. 2013).

Prevention should focus on public health education of abandoning the medical practices of applying raw animal flesh as medicinal poultices on open wounds, lesions, and eyes. Avoiding ingestion of raw flesh of frog or snake is the best prevention. Avoid drinking water from field ponds or ditches in all rural endemic areas because

Sparganosis, Fig. 3 The anterior end of sparganum with two longitudinal grooves

the unsanitary water may contain infected copepods.

Sparganum

The common name for the second larva is plerocercoid, e.g., of the tapeworm *Dipyllobothrium latum* or *Spirometra* spp., ► [Eucestoda](#). The plerocercoid larva is wrinkled, unsegmented, whitish, and ribbon shaped, 3 mm in width and up to 30 cm long. The larva is solid bodied with two longitudinal grooves (Fig. 3) at the anterior end. The larval section presents bundles of longitudinal muscle fibers scattered throughout the mesenchyme and a thick tegument.

Spirometra

A genus of tapeworm in Dipyllobothriidae, Pseudophyllidae, and ► [Eucestoda](#).

Spirometra spp.

There are several species of *Spirometra*, including *S. mansoni*, *S. mansonioides*, *S. erinacei*, *S. ranarum*, *S. decipiens*, *S. houghtoni*, and

S. proliferum. *S. mansoni* is predominately found in Asia, and *S. mansonioides* is predominately in the United States. *S. houghtoni* and *S. erinacei* are found in China and Japan, respectively. *S. proliferum* have been reported in Japan, the United States, Venezuela, and Paraguay.

Spirometra mansoni

A predominant species of the genus *Spirometra* tapeworm of dogs and cats in Asia, ► [Cestodes](#).

Spirometra mansonioides

A predominant species of the genus *Spirometra* tapeworm of dogs and cats in North and South America, ► [Cestodes](#).

Poultice

A poultice is a piece of cloth or paper with a soft substance such as a mixture of herbs on it. It is put over a painful or swollen part of the human body in order to reduce the pain or swelling.

Spathebothrium

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The species of this primitive (monozoic) tapeworm does not possess a scolex or another adhesion system. It contains, however, many sets of reproductive organs but does not form typical proglottids. It belongs to the family of Pseudophyllidae like *Triaenophorus*, ► [Ligula](#), or ► [Eubothrium](#).

Speciation

The speciation of parasites follow the general rules of speciation: if two populations of the same species are isolated from each other, they can diverge genetically because of different selective pressures or simply by genetic drift if the populations are of small size. Isolation is always necessary to prevent gene flows.

The isolation may be achieved by a physical barrier (mountain range, sea, etc.) which causes ► [allopatric speciation](#). This process is certainly the more common.

When a parasite – host system is fragmented in two or more parts, for instance by geologic events, does the host populations diverge faster than the parasite, or the parasite faster than the host, or do they diverge synchronously? There are no satisfactory answers to these questions. One can only suppose that, in the majority of cases, the parasites diverge (and finally speciate) faster than the hosts, because, during the time the populations are separated, the number of generations of the parasite is greater than that of the host, giving the parasite population more opportunities for natural selection to intervene. If the hypothesis is true, it could explain why some hosts harbour what are called “species-flocks”: if a host species has been fragmented then re-united and if the parasites have diverged to a greater degree than the host, then the different populations of the host will merge into a single population whereas the parasites will have become reproductively isolated.

In recent years, increased attention has been paid to sympatric speciation, i.e., speciation occurring without geographical separation. Sympatric speciation is not accepted by all ecologists but it has gained acceptance in recent years. It can be achieved in various ways in parasites.

One way is ► [alloxenic speciation](#). The exploitation of several host species by a single parasite species may provoke sympatric speciation if the larval stages produced in a particular host species tend to “return” to individuals of this same species. The reason for this can be a polymorphism of habitat preference, which means that some individual parasites differ genetically by

“preferences” for different species hosts. Also, different behaviours of host species may determine the isolation of parasite sub-populations which later evolve into species.

Another way is synxenic speciation, which occurs not only in a same geographical area but also in a same host species. Does synxenic speciation actually exist? Although there is no formal demonstration of its existence, one may suppose that it may happen if there is a polymorphism of habitat preference in the parasite initial population for different parts of the host organism. “Parasites account for a large part of known species diversity and are considered to have a high potential for sympatric speciation” (McCoy). The process is the same as in alloxenic speciation except that the scale is different: organ of the host instead of host species. Let us suppose for instance that in a population of an intestinal parasite, some individuals have genes which make them prefer the duodenum and others have genes which make them inhabit the jejunum; if it is the case, the individuals which exhibit one type of preference will mate only with individuals exhibiting the same preference; and so on at each generation. This is a powerful isolating mechanism. The two “sub-populations” can later diverge genetically and ultimately become different species.

Species

Group of similar individuals among which reproduction is possible and leading to further sexual reproduction in further generations.

Specificity

There is no living being which lives everywhere. In this sense, all animal or vegetal species are specific to certain ► [environmental conditions](#). In the world of parasites, being specific means being capable of exploiting a limited

range of host species (the term “specific” can be also used to define the exploitation of certain organs or parts of organs, but this acceptance is less common).

Usually, a parasite species which infects a single species of host is called “oioxenic,” a parasite which infects a range of closely related host species is called “stenoxenic,” and a parasite which may develop in or on unrelated host species is called “euryxenic.” A general rule of parasitism is that specificity is narrow, with certain exceptions.

Human schistosomes, in their adult stages, provide examples for these different types of specificity.

► *Schistosoma haematobium*, the agent of urinary schistosomiasis in Africa, is considered as strictly specific to humans, even if it has been occasionally reported in the case of baboons. This strict specificity makes *S. haematobium* a parasite that is difficult to keep in the laboratory, although at least some strains can be adapted to a few species of laboratory rodents, for instance *Meriones unguiculatus*.

S. mansoni, the agent of intestinal schistosomiasis in Africa and South America, is common in humans and, in certain foci, also parasitizes various species of rodents. For unknown reasons, this is especially true in the Caribbean and South America. In certain foci of the island of Guadeloupe for instance, the black rat, *Rattus rattus*, plays a major role in the maintenance of the parasite.

► *S. japonicum*, the agent of intestinal schistosomiasis in Asia, parasitizes nearly all mammals having sufficient contacts with water bodies. More than 40 species of mammals have been reported as hosts in continental China only. It must be stressed, however, that specificity varies in different foci. For instance, Taiwanese strains parasitize various mammals but apparently not humans, Philippine strains parasitize rodents, whereas this is rare in continental China.

The fact that, within a single genus (► *Schistosoma* in the above example), specificity varies widely, means that specificity is an adaptive character and has been selected for. However, the

way a host spectrum is selected during the course of evolution as well as the nature of selective pressures remain largely misunderstood. It is remarkable that, at the first stage of their development, in their molluscan host, the three species of *Schistosoma* mentioned above seem to be equally strictly host-specific: *S. haematobium* develops only in pulmonates of the genus *Bulinus* (with a local exception in North Africa and Spain), *S. mansoni* in pulmonates of the genus *Biomphalaria*, *S. japonicum* in prosobranchs of the genus *Oncomelania*.

Host specificity has important implications for the geographical distribution of parasites. This is particularly obvious in the case of schistosomes: during the sixteenth and seventeenth centuries, tens of thousands of black people were forced to leave Africa and transported into the New World. Most of them were infected by one or the other of the two main species of african schistosomes *S. mansoni* and *S. haematobium*. However, only *S. mansoni* became established into the New World (Caribbean and South America) because snails of the genus *Biomphalaria* were present. On the other hand, *S. haematobium* never became established in America because of the absence of representatives of the genus *Bulinus*.

Certain groups, such as monogeneans (platyhelminths parasitic on gills or skin of fish, more rarely endoparasitic in amphibians and turtles) are extremely specific (most species parasitize only one host species). The improvement of chemical analysis (allozymes, DNA sequences) has often shown that species which were reported from a variety of hosts were in fact complexes of closely related but strictly separated species. Cestoda are another group characterized nearly always by a narrow specificity. Other groups, such as digeneans (see the case of *Schistosoma* above) and nematoda, comprise both oioxenic, stenoxenic, and euryxenic species. The case of parasites with complex life cycles is specially intriguing, because the host spectrum can be extremely different at different steps of the cycle. In digeneans for instance, specificity is narrow towards the first host (mollusc), but variable at the other steps of the cycle.

An intriguing question concerning parasite specificity is: why have certain parasites a narrow specificity and others a wide one? As a matter of fact, the question is not particular to parasites: why are certain plants restricted to precise environmental conditions, whereas others are ubiquitous, why does the koala eat only eucalyptus leaves and the pig nearly anything? The question is thus: why are there specialists and generalists in life? In terms of natural selection, the answer is that it is sometimes advantageous to be a specialist and sometimes to be a generalist. But this answer is unsatisfying. At a first glimpse, it seems that it should be always better for a parasite to be relatively unspecific, but this is to forget that there is a cost involved in generalism (investment in [evolution mechanisms](#) adapted to different immune systems, increased competition with other parasites, etc.).

Availability of computers and the development of methods of “comparative analysis” have permitted the investigation of ecological factors that determine specificity. For instance, after investigating into the confounding effect of the sampling effort (study intensity), Poulin showed that there is a positive relationship between the number of potential hosts (i.e., phylogenetically related hosts) and specificity. Although a phylogenetic conservatism in an ecological character such as specificity has been demonstrated, detailed explanation of differences in specificity is not presently available.

Spelotrema

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of digenetic trematodes of the family Microphallidae that parasitize in the intestine of shorebirds.

Spelotremabrevicaeca

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

There are rare cases of human infections, even though the final host is unknown.

of insects (► [Insects/Reproduction](#) ► [Pulex irritans](#)).

Spermalege

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

See Ribaga organ of bed bugs. This pocket-like structure is situated below the body cover and has no opening to the outside. Males try to fill it (by help of their hook-like ► [aedeagus](#)) with sperms (by penetration of the body wall).

Spermatophore

Small packet of sperm, produced by some animals having internal fertilization, e.g., ► [ticks](#) (► [Ticks/Reproduction](#)).

Spermatozoa

Male sexual gametes of metazoans that are produced during a peculiar spermiogenesis. They are motile (by help of a flagellum or pseudopodium) and thus able to reach the female gamete (the oocyte), ► [Platyhelminthes](#), ► [Nematodes](#), ► [Insects](#), ► [Ticks](#).

SPf66

Polymerized chimera peptide (► [Malaria/Vaccination](#)).

Spermatelosis

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This term is used as synonym for ► [capacitation](#) (the last step of spermatogenesis in ticks).

Sphaerostoma Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Latin: *sphericus* = spherical; Greek: *stoma* = mouth.

These trematodes (which reach a length of only 4–5 mm) live in the intestine of fresh water fish (carp, perch, eel, and pike). Their first intermediate hosts are water snails (e.g., *Bulimus* species), and second intermediate hosts are leeches

Spermatheca

A sac for sperm storage (surrounded by a chitin capsule), e.g., in the female reproductive tract

(*Herpobdella* sp.). Since these trematodes mainly feed fluid contents of the intestine, damages are rare or absent. Treatment – if necessary, depending on the amount of excreted eggs ($76 \times 60 \mu\text{m}$) – can be done by Tremazol[®] (praziquantel in fluid formulation, Fa. Alpha-Biocrine, Düsseldorf).

Sphirion

Genus of parasitic crustaceans reaching a size of 6 cm being anchored inside the muscles of freshwater fish.

Spicules

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Latin: *spiculum* = thorn.

The spicules are characteristic copulatory structures of male nematodes (► [Nematodes](#)/ Figs. 12 and 13). In most nematodes there are two spicules, which often differ in length and shape, but in some species only a single spiculum (Latin = peak, arrow) is found (► [Nematodes](#)/ Fig. 13). The spicules are needle shaped and consist of thick cuticular material which surrounds a cytoplasmic core with nerve processes. The nerve endings are covered by cuticular material. In many species the spicule wall is bent to form a hollow needle with an opening at its base and tip. The spicules are formed in a dorsal sac of the ► [cloaca](#) called the spicular pouch. The spicules can be moved back and forth by accessory muscles and during copulation they are inserted into the female vulva. A thickening of the dorsal wall of the spicular pouch, the ► [gubernaculum](#), stabilizes the protruded spicule. Additional copulatory

Spicules, Fig. 1 Light micrograph of the bursa copulatrix (BC) of hookworms showing the two spiculae (SP). ST stabilization horns

structures are found in some groups (► [Nematodes](#)/Reproductive Organs) (Fig. 1).

Spiders

► [Amandibulata](#); Chelicerata.

Spilopsyllus cuniculi

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

From Greek: *spilos* = spot, *psyllos* = flea.
► [Flea](#) of rabbits, rodents, hare (Fig. 1).

Fig. 1 Head and first thorax segment of the rabbit flea. *A* antenna, *AF* antenna groove, *AU* eye, *WZ* head ctenoides

Spinal Collar Fluke

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Trivial name for the adults of the trematodes of the genus *Echinostoma*.

Spines

The tegumental surface of several trematodes is provided with proteinaceous scales, which in light microscopy look like spines (*Fasciola*, ► *Paragonimus*, ► *Heterophyes*). These spines apparently are used as holdfast system besides the two suckers.

Spinosad

Chemical Class

Macrocyclic lactone (12-membered macrocyclic lactone, spinosyns).

Mode of Action

Nicotinic acetylcholine receptor agonist.

► [Ectoparasiticides: Agonists and Antagonists of Cholinergic Transmission](#).

Spinose Ear Tick

Otobius megnini, the bite of which may introduce severe secondary bacterial ear canal infections in cattle (► [Tick Bites: Effects in Animals](#)).

Spinturnix

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Genus of mites, which parasitizes on bat species:

– *Spinturnix myoti* at the greater mouse-eared bat (*Myotis myotis*)

- *Spinturnix bechsteini* at the Bechstein's bat (*Myotis bechsteinii*)

Both hosts have largely different social systems with respect to group size, mating system, and dispersal patterns. Thus there have been developed in both – bats and single mite species – completely different population genetics developed by coevolutionary pressure.

Spiny Bulbus Worm

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Trivial name of the adults of *Gnathostoma* species.

Spinturnix myotis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Latin: *spinosus* = with many thorns; *turnix* = bird: *Coturnix coturnix*; Greek: *mys*, *myos* = mouse.

This mite (Acari, Gamasida) parasitizes the wings of bats. It got its name, since it lives on the greater mouse-eared bat *Myotis myotis* and of related species reaching a body length of about 1 mm. These mites are highly specialized and reproduce exclusively on the wing or tail membranes, and all their developmental stages (protonymphs, deutonymphs, and female/male adults) feed on blood of their hosts being stored in the midgut and its branches reaching even into the legs. Nearly all bats are infected during bat breeding seasons due to overcrowded bat colonies.

Spiny Intestinal Fluke

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Trivial name for the adults of genus *Metagonimus*.

Spiracles

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes the openings of the tracheal systems of insects to the body surface. The shape of the posterior spiracles of fly maggots may be used for species determination (Fig. 1).

Spiracles, Fig. 1 Diagrammatic representation of the posterior spiracles of some important flies with their species-specific slits through which air may enter

Spiramycin

Drug used in toxoplasmosis and cryptosporidiosis.

Spirocerca lupi

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Spirocerca arctica

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *speira* = winding; *kerkos* = tail. Latin: *lupus* = wolf.

Geographic Distribution/Epidemiology

Own northern species or race of *Spirocerca lupi*.

Common parasite of dog, foxes, and wolves, but also in cats and wild canids and felids, especially

in warm countries, e.g., Southern Europe, the USA, South America, Asia, and Africa. In some tropical countries, up to 80 % of dogs are infected. Infections due to larvae are common in many vertebrates including humans. A second species (*Spirocerca arctica*) has been demonstrated in canids in Northeast Europe.

Morphology/Life Cycles

The adult worms appear bloodred (♀ = 5–8 cm; ♂ = 3–5 cm) and live in groups in granulomas of the distal esophagus (and rarely also in the wall of the stomach and upper intestine). Their esophagus is divided into an anterior muscular portion and a posterior glandular region. The males possess caudal wings and two differently sized spicula (2.5 and 0.6 mm). The vulva of the female is found in the anterior region of the esophagus. The females excrete eggs within feces and vomiting fluids, which have a thick shell, measure about $35 \times 15 \mu\text{m}$ and contain already the larva 1 (Fig. 1). Coprophagous beetles (e.g., *Geotrupes* species) or related arthropods are used as intermediate hosts, where the larva 3 is developed inside their hemocoel. Dogs and other hosts are infected when ingesting such hosts. The larvae 3 were set free in the stomach, enter the stomach wall, and migrate inside the blood vessels until the breast aorta where the third and fourth molts occur. About 3 months later, they migrate into the submucosa of the esophagus, where they form worm knots (granulomas) and reach maturity.

Symptoms of Disease (Spirocercosis)

Occurrence of dove-egg-size nodules inside the esophagus wall and aneurisms of blood vessels lead to loss of blood and disturb feeding and growth. Vomiting is common, loss of weight as well. Furthermore, breathing is considerably disturbed, and tumors are induced. Especially young dogs are highly endangered. Already, infections with 50 larvae may lead to death.

Diagnosis

Microscopical demonstration of the typical eggs (Fig. 2) inside the feces after use of concentration methods (S.A.F.C., ► [flotation](#)).

Infection

Oral uptake of eggs within coprophagous beetles. If these beetles are ingested by reptiles, birds, etc., these animals may become paratenic hosts.

Prophylaxis

Difficult in free-roaming dogs, which might ingest infected beetles.

Incubation Period

Three to four months.

Prepatent Periods

Five to six months.

Patency

Years.

Therapy

Depending on the size of granulomas, surgical removal may become necessary. However, treatment with doramectin (3x at 3 week intervals with 0.2–0.5 g/kg bodyweight) leads to clinical healing and final disappearance of the worm knots.

***Spirocerca lupi*, Fig. 1** *Spirocerca lupi*. Diagrammatic representation of the life cycle. 1, 2 In dogs that have ingested infected dung beetles or paratenic hosts (6, 8), the larva 3 (2) is set free from the surrounding cyst material. 3 The larva 3 penetrates the stomach wall and migrates to the gastric arteries and finally travels upstream to the aorta (A), where mostly several larvae spend up to 3 months in the aorta wall forming nodules. Here, the larva 4 is formed and finally the young adult worms emerge from the nodules. This process results often in the formation of an aneurism. Ruptures may lead to immediate death. 4 Starting about 3–7 months after infection, the larvae

penetrate the aorta wall and enter from outside the esophagus (E), where nodules are formed, which contain several adult worms of different sex. Adults slip out from the nodules via a small opening to lay eggs into the esophagus lumen. 5 Eggs can be found in the feces and contain already the larva 1. 6, 7 If dung beetles ingest these eggs, larvae 1 encyst inside the beetle and develop inside these cysts the third larval stage = infectious stage. 8 If such beetles are swallowed by paratenic hosts (frogs, rats, lizards, birds, etc.), these larvae are stored there and can also infect dogs, when swallowing such paratenic hosts. A aorta; E esophagus (After Austin et al. 2013)

***Spirocerca lupi*, Fig. 2** Light micrograph of an egg of *S. lupi* containing the larva 1

Spirometra erinaceieuropaei

Name

Greek: *speira* = winding, *metra* = uterus.

Life Cycle

This worm (40 cm long) lives in the small intestine of carnivores in Europe, Asia, Australia. First intermediate hosts are rodents, amphibia, second intermediate hosts are rodents, pigs, monkeys.

Prepatent period

2–3 weeks. In humans the plerocercoids = spargana may be found in various organs.

► [Eucestoda](#).

Spirometra mansonoides

Tapeworm of dogs, cats in North and South America. ► [Cestodes](#).

Spirotrunculus

Name

Latin: *spira* = winding, *nucleus*.

Genus of flagellates of birds and of fish. *S. meleagridis* is synonym to *Hexamita meleagridis* (6–12 µm, 6 anterior, 2 posterior flagella), *Spirotrunculus* spp. from the intestine of fish show the same morphology (Figs. 1 and 2), they parasitize in the intestine and may lead to important losses in ornamental fish cultivation. Transmission occurs via cysts with a size of 4–5 × 6–7 µm. ► [Diplomonadida](#).

Spiruroid Type X Larva

Larva of a spiruroid larva which causes syndromes of larva migrans externa (in skin) and larva migrans interna in the ileum and in the eye of humans in Asia. These type X larvae measure $6-8 \times 0.1$ mm and possess 2 tubercles at the tail and 2 pseudolabia at the head. Symptoms occur 2–9 days after eating raw squid.

Therapy of Fish

Flagellol of Alpha-Biocare, Düsseldorf.

Spirorchis Species

► [Digenea](#), which lay fully embryonated eggs.

Spiruoidea: Gongylonematidae

Superfamily of ► [nematodes](#). Especially members of the family ► [Gongylonematidae](#) may infect humans, e.g., the “gullet worm” of domestic animals may occur in the esophagus and/or stomach and becomes embedded in the mucosa. Infections occur (also in humans) by eating the intermediate hosts (beetles).

Splendidofilaria

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of filarial worms of birds; the adults live in the connective tissues close to the joints, and their microfilariae are found inside the blood. The latter are unsheathed and measure about 120 µm in length.

Splendidofilaria fallisensis

Species (syn. *Ornithofilaria*) of filariid nematodes in the subcutis of ducks in North America.

Splenomegaly

Symptom of disease due to infections with ► [African trypanosomiasis](#), babesiosis, ► [malaria](#) in children, ► [visceral leishmaniasis](#).

Spliced Leader

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The spliced leader (SL) is a small nucleotide sequence (mini-exon) that is required for protein-coding gene expression. The SL is encoded as part of a donor RNA gene (SL RNA) and transferred to pre-mRNA during *trans*-splicing to generate the mature 5' ends of mRNAs (► [Trans-Splicing](#), Fig. 1). SL addition is unique to kinetoplastids, euglenoids, ► [nematodes](#), and

flatworms. In kinetoplastids, it serves to resolve polycistronic into translatable monocistronic transcripts and may have the same function in helminths. SL RNA in *Trypanosoma brucei* is 140 nucleotides long and is encoded by about 200 genes organized in tandem repeats of 1.35 kb. SL sequences have similar structures in different organisms and resemble small nuclear RNAs (snRNAs) but vary in length among different species. In kinetoplastids, every nuclear-derived mRNA carries a 39–41 SL nucleotide sequence at its 5' terminus, while helminth SLs are 22 and 36 nucleotides long, respectively.

SPN

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Subpellicular network of motile stages of ► [Apicomplexa](#). See ► [Alveolins](#).

Spores

From Greek: *spora* = seed. ► [Amblyospora](#), ► [Microsporidia](#), ► [Coccidia](#), ► [Myxozoa](#), ► [Ascetospora](#), ► [Haplosporidia](#).

Sporoblast

Stage prior to formation of sporocysts in ► [Coccidia](#) or ► [Spores](#) in ► [Microsporidia](#).

Sporocyst

Most common meanings are:

- Cyst inside oocysts of ► [Coccidia](#) containing the infectious stages = sporozoites (► [Gregarines](#)).

- Developmental stage of digenean life cycle (► *Digenea*/Life Cycle) inside the first intermediate host snail. These sporocysts produce depending on the species – daughter sporocysts, ► *rediae*, or ► *cercariae*. The latter leave the snail and may become infectious to a second intermediate host (e.g., in the case of *Clonorchis*), to the final host (e.g., ► *Schistosoma*), or are attached at plants to become metacercariae (e.g., ► *Fasciola hepatica*, ► *Fasciolopsis buski*).

Sporogony

Asexual reproduction of ► *Coccidia*, ► *gregarines* and ► *Microsporidia*. The ► *zygote* – the only diploid stage in the life cycle of ► *Apicomplexa* – produces infectious sporozoites by means of meiosis followed by numerous divisions.

Sporokinete

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

In the piroplasm genus ► *Babesia* and some adeleidean ► *Coccidia* (e.g., *Karyolysus*) the motile ► *zygote* (= ► *kinete*) grows up to a spherical stage (= sporont), which divides into several motile stages identical in appearance to the zygotic kinete. These new kinetes are now called sporokinetes (Fig. 1).

Sporokinete, Fig. 1 Diagrammatic representation of a sporokinete of ► *Theileria* species being formed from a zygote. EN = inner layer of pellicle; ER = endoplasmic reticulum; MI = mitochondrion; MN = micronemes; MPA = micropore-like structure; N = nucleus; PE = pellicle; PR = polar ring system; SMT = subpellicular microtubules; UIM = interruption of the inner membrane; VG = food vacuoles

Sporozoa

Synonyms

Apicomplexa, a subgroup of Alveolata.

Sporozoite

Motile banana-shaped stage within sporocysts of ► *Coccidia*. Their fine structure is practically identical to that of ► *merozoites*. In addition to the organelles of merozoites they possess 1 or

2 (depending on the species) large ► [reserve granules](#) (= ► [refractile bodies](#), crystalloid bodies). Having reached a new host the sporozoites enter host cells and start reproduction by ► [schizogony](#).

Sporozoite Formation

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The formation of sporozoites of coccidian species occurs differently depending on the species. In species which produce thick-walled oocysts, which are excreted within the feces of their hosts (e.g., *Toxoplasma*, ► [Sarcocystis](#), ► [Eimeria](#), ► [Isospora](#)), the sporozoite production occurs inside another compartment (= sporocyst) from a sporoplasm with 2, 4, 8, etc. nuclei (see ► [Coccidia](#)). In ► [Babesia](#) and ► [Theileria](#) species, which are transmitted within the saliva of ticks and which are previously produced inside salivary gland cells after a zygote (► [kinete](#)) had entered, the sporozoites are formed at the periphery of multinucleated sporoplasms. Each sporozoite develops from protruding elevations at the periphery of the sporoplasm. During this process, a peripherally located nucleus is included. In many cases, the last nuclear division gives rise to two sporozoites, where each start formation above one of the two tips of this dividing nucleus.

The sporozoites of ► [Plasmodium](#) species, which are formed inside so-called oocysts at the outer surface of the intestine of the vector mosquito, are developed apparently in a very similar way as was shown by Schrével et al. (2007), when studying serial sections of oocysts of *Plasmodium berghei* in *Anopheles stephensi* mosquitoes. During these studies, an apparently very basic vesicle

trafficking process was observed and is probably the basic process of all developmental motile stages of coccidians.

References

Schrével J et al (2007) Vesicle trafficking during sporozoite development in *Plasmodium berghei*: ultrastructural evidence for a novel trafficking mechanism. *Parasitology* 135:1–12

Sporozoite's Liver Invasion

Malarial sporozoites that enter the liver parenchyma of their hosts have to pass through a cascade of events: binding to extracellular matrix proteoglycans, passage through Kupffer cells, transmigration through several hepatocytes until the final cell is invaded. The sporozoite thus exploits the properties of the liver to evade the immune system.

Sporulation

The asexual formation of sporocysts and sporozoites inside oocysts of ► [Coccidia](#) is called sporulation with respect to the process and its timing. It is synonymous to ► [sporogony](#) which reflects the phase inside the life cycle.

Spotted Fever

Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Stomoxys calcitrans (► [Diptera](#)) (Figs. 1 and 2).

Stable Fly, Fig. 1 Macrophoto of *Stomoxys calcitrans* on skin

Stable Fly, Fig. 2 Macrophoto of *Stomoxys calcitrans* on a glass plate from below

Stage Conversion

This phenomenon, that a parasite converts from one life cycle stage to another (e.g., from tachyzoite to bradyzoite or inverts in *Toxoplasma*), is steered by a change in gene expression.

Stare Eyes

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This disease occurs in fish, when cercariae of the genera *Diplostomum*, *Tylodelphys*, *Posthodiplostomum* and eight others enter fish eyes and introduce metacercaria formation. Although these metacercariae measure only about 1 mm in diameter, the reactions of the fish introduce nodules of several mm in diameter, which protrude the eyes, which become grayish and thus reduced in light reception. The adults of these worms live in birds as final hosts and in water snails as intermediate hosts. **Treatment** can be done in aquaria by Tremazol® of Fa. Sera, Heinsberg, Germany (containing praziquantel).

STARP

Sporozoite-threonine- and asparagine-rich protein of *Plasmodium* sporozoites.

Stegomyia

Genus of mosquitoes. Recently the species *Aedes aegypti* was changed to *Stegomyia aegypti*.

Stegomyia albopicta

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Species of mosquitoes; synonym for ► *Aedes albopictus* (tiger mosquito), e.g., vector of yellow fever and Dengue fever.

Steinernema

Genus of entomopathogenic ► [Nematodes](#), which contain symbiotically living enterobacteriaceae of the genus *Xenorhabdus*. Inveniles of the worm enter the insects and often kill them during development just after having produced progeny as adults. Fitness of the worms is apparently dependent on their bacteria.

Steinia ovalis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The species that is often found in the intestine of dark beetles (*Tenebrio molitor*) and is often used for teaching purposes

Stellachasmus falcatus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This trematode species has a similar life cycle like ► [Heterophyes](#) species. It occurs in Thailand and uses dogs, cats, and fish-feeding birds. The adult worms reach only a size of 0.5×0.2 mm but may occur in masses. Intermediate hosts are snails of the genus *Thiara* and fishes of the mugilid group.

Stellantchasmus

Genus of the trematode family Heterophyiidae.

Stellantchasmus formosanus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Rare cases of human infections of this species and *S. pseudocirratus* have been described.

Stemma

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The larval egg of holometabolic insects.

Stenoxeny

From Greek: *stenos* = narrow, *xenos* = guest, foreigner. Species of this kind have a high host specificity.

Stephanofilariosis

Several species of *Stephanofilaria* (► [Filiariidae](#)) cause cutaneous lesions similar to those of onchocercosis in cattle, but on different parts of

the body. The adult worms live in cystic diverticula at the base of the hair follicles. The lesions develop over several years. Initially they appear as small papules which coalesce to form a larger lesion covered with crusts. Eventually the skin becomes thickened, there is loss of hair, hyperkeratosis, an ulcerating core, and haemorrhage. The lesions are mildly pruritic. After healing, the affected areas remain as hairless lichenified plaques.

Therapy

► [Nematocidal Drugs, Animals](#).

Stephanurus dentatus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This species occurs in cysts of the kidneys, bladder, and excretory channels of pigs. The infection (mainly in tropical and subtropical regions but not in Europe) occurs by actively skin-penetrating larvae 3 or by ingestion of paratenic hosts such as earthworms or cockroaches, etc. The symptoms of disease may be severe. Treatment can be done by application of ivermectin or doramectin (both by ingestion of 0.3 mg/kg bodyweight).

Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Stokes, Adrian (†1927)

English microbiologist and specialist for spirochaetes/leptospire, which were at first claimed to be the agents of the yellow fever. During his investigations of the suggested vectors (tiger mosquitoes of the genus *Aedes*) he died from the

Name

Greek: *habros* = smooth, thin; *trichos* = tiny hair; *nema* = filament. Latin: *musca* = fly; *maior* = larger; *megastoma* = large mouth; *microstoma* = small mouth; *axis* = axis.

English: Stomach worms. **Drasche**, Richard (1850–1923) Austrian Scientist.

Geographic Distributions/Epidemiology

Worldwide; in farmed animals local epidemics occur.

Morphology/Life Cycle

- *Habronema muscae*; *H. majus* (syn. *microstoma*); reach a length of 25 mm (♀) and 15 mm (♂).
- *Draschia megastoma*: ♀ = 13 mm, ♂ = 10 mm.
- *Trichostrongylus axei*: ♀ = 8 mm, ♂ = 6 mm.

Habronema and *Draschia* live in nodules in the stomach wall or are attached there in the mucous layer (*Trichostrongylus*). The females excrete embryonated eggs (*Trichostrongylus*), larvae-containing eggs (*Habronema*), or already free larvae (*Draschia*), which all can be found in the feces of the hosts. For *Habronema* and *Draschia*, fly larvae (e.g., *Musca*) are used as intermediate hosts, which as adults transmit the infectious larvae 3 onto the lips of horses. *Trichostrongylus axei* does not need an intermediate host, since the infectious larva 3 develops outside of a body and is ingested with contaminated food.

Symptoms of Disease

Slight infections remain subclinical; however, in cases of large numbers of worms the following symptoms may be recorded: colics, catarrhalic gastritis, and loss of weight. In case of skin lesions due to invasions of larvae of *Habronema* and

Draschia, the clinical aspect of so-called **summer-sores (wounds)** occur, which mostly heal badly, remain wet thus attracting licking insects, which then may transmit a broad spectrum of agents of diseases. *T. axei* induces typical lesions in the stomach described as a “gastritis chronica hyperplastica et circumscripta.”

Diagnosis

Microscopical demonstration of the thin-shelled eggs (see ► [Worm eggs](#) of horses) respectively larvae in feces by help of the Baerman technique.

Infection

Oral uptake of larvae 3 in food (*Trichostrongylus*); fly transmission of larvae 3 onto mouthparts of horses.

Prophylaxis

Regular removal of feces from stables; fly control around horses.

Incubation Period

1–4 weeks.

Prepatent Period

2 months for *Habronema* and *Draschia*; about 3 weeks for *T. axei*.

Patency

4–5 months.

Therapy

- *T. axei*: **ivermectin** 0.2 mg/kg bodyweight; **tiabendazole** (50 mg/kg bodyweight) or **cambendazole** (20 mg/kg bodyweight).
- *Habronema* and *Draschia*: for stages in the stomach: ivermectin; for stages in skin lesions: ivermectin, 10 % metrifonate solution; 1:20 solution of MiteStop®.

Stomoxys, Fig. 1 LM of an adult *Stomoxys calcitrans*

Stomatodaeum

Ectodermal portion of mouth, ► [Arthropoda](#),
► [Insects](#).

Stomoxys

Name

Greek: *stomoxys* = with pointed mouth.

Classification

Genus of the fly family Muscidae, subfamily Stomoxynae = biting flies.

Life Cycle

The worldwide occurring species *S. calcitrans* (= stable fly) reaches a size of up to 7 mm and is

found mainly in stables (Fig. 1). After bloodsucking the females deposit 60–100 eggs per batch (800 in total) onto the faeces of cattle, horses, or degenerating plants. Within 3–7 weeks the new generation develops. Females feed two times per day (often double their own weight) and thus introduce a considerable blood loss, if they occur in masses. The larvae and pupae overwinter at protected places in the stables or close by. ► [Diptera](#), ► [Insects](#), Fig. 9C.

Stomoxys calcitrans: Transmission Activity

Streblidae (Bat Flies)

Carl W. Dick

Department of Biology, Western Kentucky
University, Bowling Green, KY, USA
Integrative Research Center, Field Museum of
Natural History, Chicago, IL, USA

Overview

The family Streblidae, or bat flies, is a small family of Diptera containing members that are exclusively ectoparasitic upon bats. The Streblidae, along with three other fly families (Nycteribiidae, Hippoboscidae, and Glossinidae), are members of the calyptrate superfamily Hippoboscoidea. Hippoboscoid Diptera are obligate blood feeders that prey on mammals and birds (Dick and Patterson 2006). So far, streblid flies have not been implicated in the maintenance or transmission of zoonotic agents (Dick and Dittmar 2014).

Morphology

Streblid flies possess several distinguishing morphological features, but across the family, these can be highly variable (Figs. 1, 2, 3, and 4; Wenzel and Peterson 1987). Generally, all species possess relatively small eyes with few facets, are uniformly light tan in color, and possess strong, bristlelike setae. Some forms are the typical muscoid type, whereas others are strongly dorsoventrally compressed and others strongly laterally compressed and flea-like. Species of one genus, *Ascodipteron*, even become secondarily endoparasitic. After mating, females lose their wings and legs and burrow subdermally into the host where they reproduce. Streblids also vary tremendously in wing structure. Most species possess fully functional wings, but others possess nonfunctional, vestigial wings which are either stenopterous (long and narrow) or brachypterous (short and broad) in form. Members of one genus, *Paradyschiria*, are completely wingless. During

Streblidae (Bat Flies), Fig. 1 Female *Megastrebla gigantea* (Speiser, 1899) (Streblidae: Brachytarsiniinae) (Photo reproduced from Dick and Dittmar 2014)

the evolutionary history of extant Streblidae, wings have been lost or become vestigial at least five times. Even though most species possess functional wings, streblids are generally weak flyers. Like the nycteribiids, some streblids possess ctenidia or combs, particularly on the posteroventral margin of the head. Species in possession of such ctenidia almost always specialize on the furred regions of the host's body, where the combs function as holdfast organs.

Reproduction

Formerly known as the Pupipara, this group of flies is characterized by a viviparous developmental system, which is unique among flies. The larval stages develop inside the female, where they are nourished by intrauterine glands. Three larval

Streblidae (Bat Flies), Fig. 2 Female *Aspidoptera phyllostomatis* (Perty, 1833) (Streblidae: Trichobiinae) (Photo reproduced from Dick and Dittmar 2014)

Streblidae (Bat Flies), Fig. 3 Male *Megistopoda aranea* (Coquillett, 1899) (Streblidae: Trichobiinae) (Photo reproduced from Dick and Dittmar 2014)

instars develop, and the fully grown (third instar) larva is deposited by the female and quickly develops into a pupa. In most streblids, single larvae are deposited inside the bat's roosting

Streblidae (Bat Flies), Fig. 4 Female *Nycterophilia bilineata* Reeves, Loftis, and Beck, 2012 (Streblidae: Nycterophiliinae) (Photo reproduced from Dick and Dittmar 2014)

environment, and the female depresses her abdomen against the larva, helping it to adhere to the substrate. Following about 3-week development, the unfed (teneral) adult emerges from the puparium and must locate a host bat for purposes of feeding and, later, finding a mate. In the secondarily endoparasitic genus *Ascodipteron*, mature larvae are extruded from the encysted female and fall to the floor of the bat's roost, where they pupate. Streblids are generally understood to live more or less continuously on their hosts as adults, excepting for times when females leave the host to deposit a mature larva. However, there is evidence that at least in some large roost caves, a substantial number of adult flies of both sexes remain in the roost during bat foraging bouts. The life history of one streblid species, *Megistopoda aranea*, is known in some detail. Females are known to deposit terminal instar larvae in the roost, relatively near to roosting bats. Following an average of 23 days, the adult emerges from the puparium. In many cases, female flies were observed mating immediately after larval deposition. The interval between successive larval depositions averaged about 10 days. Longevity of male and female

streblid species remains unknown (Overal 1980; Fritz 1983).

Diversity and Geographical Distribution

Streblidae are distributed worldwide and currently include 5 subfamilies, 32 genera, and 228 described species (Dick and Patterson 2006). Two subfamilies, Nycteriboscinae (50 species) and the Ascodipterinae (21 species), are exclusively limited to the eastern hemisphere. Conversely, the remaining three subfamilies, Nycterophiliinae (7 species), Streblinae (35 species), and Trichobiinae (115 species), are exclusively limited to the western hemisphere. Thus, even at the subfamily level, the Old and New Worlds share no streblid taxa. Robust phylogenies for the Streblidae are still lacking, but an understanding of their relationships is developing (Dittmar et al. 2006). There is strong evidence that the family (as currently structured) is decidedly non-monophyletic. Under the developing picture, some of the Old and New World subfamilies of streblids are sister taxa, with three monophyletic clades separating the subfamily Nycteriboscinae, the Old World Ascodipterinae + New World Nycterophiliinae, and then the New World subfamilies Trichobiinae + Streblinae (Dittmar et al. 2015).

Host Distribution and Specificity

The deeper host associations evident in the Nycteribiidae are not as clear in the Streblidae. This may be a consequence of a generally incomplete understanding of streblid fly relationships at the subfamily level. Only one genus of Streblidae (*Megastrebla*) is associated with Old World fruit bats of the family Pteropodidae. All other streblids are parasites of Microchiroptera. In the western hemisphere, where streblids are the most diverse in terms of species and overall body form and ecology, they are particularly diversified on the bat family Phyllostomidae. However, a few

species are also known to parasitize bats of the families Emballonuridae, Vespertilionidae, Molossidae, Natalidae, Furipteridae, Mormoopidae, and Noctilionidae (Dick and Patterson 2006). Historically, streblid species were assumed to be quite catholic in their host associations, largely because bat species roost in mixed-species groups and the largely volant flies have ample opportunity to switch host species (Dick 2007). More recently, as sampling and survey methods have become more carefully executed, bat flies are increasingly understood to be highly specific to individual host species (Dick and Patterson 2007).

Streptocara

Genus of the nematode family Acuariidae.

Streptomyces avermectinius

Fungus, out of which the avermectines had been isolated in the year 1975 (by Professor Omura, ► [Kitasato](#) University, Japan), starting a furious career in nematocidal drugs.

Streptopharagus

Genus of the nematode family Spirocercidae.

Streptothricosis

Bovine streptothricosis is associated with the tick species *Amblyomma variegatum*. It is an acute or chronic, local or progressive, and sometimes fatal, exudative dermatitis of cattle and other domestic and wild hosts caused by the bacterium *Dermatophilus congolensis*. It is characterized by a serious exudate which dries to mat the hair into paintbrush-like tufts, or to form crusts and thick scabs. It is widespread in tropical areas of vector distribution, where its appearance is mainly seasonal, occurring more during the rainy season.

Therapy

► [Antibiotica](#).

Strigeidae

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Latin – *strigatus* (striped).

The members of this family are rather tiny 1–3 mm long digenetic trematodes, the body of which seems to be divided in two portions since a groove is surrounding the midbody region. The anterior portion contains the mouth sucker, the ventral sucker plus an additional adhesion organ (= tribocytic organ). The posterior portion contains inside the sexual organs and outside their exits. The adult worms (e.g., *Apatemon* (syn. *Strigea*) *gracilis*, *Cotylurus cornutus*, *Parastrigea robusta*, etc.) live in the intestine of ducks, goose, pigeon, and several water birds. Their eggs are operculated. The miracidia enter freshwater snails, while freshwater fish (*Apatemon* spp.), other snails or leeches (*Cotylurus* spp.), respectively, and larval/adult frogs (*Parastrigea* spp.) are used as second intermediate hosts. Thus this type of life cycle is called triheteroxenous.

Members of the ► [Eucestoda](#) (e.g., *Echinococcus* species) show a characteristic body differentiation into ► [scolex](#), neck, and strobila consisting of a few (e.g., *Echinococcus*) up to 4,000 proglottids (e.g., *Diphyllobothrium*).

Strobilocercus

Syn. Cysticercus fasciolaris, which is the larva of the cat tapeworm *Taenia taeniaeformis* (► [Cestodes](#)). These larvae appear with a 3–20 cm long segmented proglottis-like band emerging from a terminal bladder. This cysticercus occurs in the liver of the intermediate hosts: rodents.

Strongylids of Horses

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *strongylos* = rounded.
The term describes the cylindrical appearance of the worm body.

General Information

In the colon of horses and other equids parasitize so-called large and small strongylids, which belong to the most common and most important nematodes. The large ones are characterized by the fact that they migrate through the body of their hosts, while small strongylids have a direct inner life cycle (however, a histiotropic phase is passed in the wall of the colon before maturity is reached in the lumen of the intestine).

Large Strongylids of Horses (► [Strongylus Species](#))

The four species (*Strongylus vulgaris*, *S. asini*, *S. equinus* and *S. edentatus*) measure as females about 15–50 mm in length and reach as males a length of about 10–35 mm. Infection occurs by

Strongylids of Horses, Table 1 Species of small and large strongylids of horses

Large strongylids	Subfamily Strongylinae: <i>Strongylus asini</i> , <i>S. edentatus</i> , <i>S. equinus</i> , <i>S. vulgaris</i> . (Total: 4 species)
Small strongylids	Subfamily Strongylinae: (♂ = 6–20 mm, ♀ = 7–29 mm) E.g., <i>Bidentostomum</i> , <i>Craterostomum</i> , <i>Oesophagagodontus</i> , <i>Triodontophorus</i> .
	Subfamily Cyathostominae (♂ = 4–19 mm, ♀ = 5–22 mm) E.g., <i>Cyathostomum</i> , <i>Caballonema</i> , <i>Coronocyclus</i> , <i>Cylicostephanus</i> , <i>Cylindropharynx</i> , <i>Cylicodontophorus</i> , <i>Petrovinema</i> , (+5-6 further genera, in total: ~51–53 species)
	Subfamily Cyalocephalinae (♂ = 7–10 mm, ♀ = 8–13 mm) <i>Cyalocephalus capitatus</i> .

lamellae, CR ring-like protrusions of cuticle, IL inner ring of lamellae, MH mouth cavity, OM muscles of esophagus, ZL tooth-like cuticular protrusions

oral uptake of eggs containing already the sheathed larva 3, which hatches from the egg inside the intestine and penetrates into the wall of the cecum or colon, where they start a migration phase after having developed into larva 4. After this wandering phase of several months (including a hypobiotic phase) they re-enter the colon and molt to become larvae 5 (preadults) and finally reach maturity.

The **prepatent period** may last 6.5–11 months, while their **patency** is mostly rather short (1–1.5 years).

Small Strongylids of Equids

The 60 species of the small strongylids belong to 3 subfamilies with about 60 single species (see Table 1). The adult females are much smaller than those of the large strongylids, reaching about 5–11 mm at the maximum, while the males are even smaller (4–15 mm in length). The hosts swallow eggs containing sheathed larvae

3, which become desheathed during hatching. Just after being freed from the egg shell the sheathless larvae 3 enter the mucosa or submucosa inside the colon or cecum. There they stay for a histiotropic phase for 1–2 months before they re-enter the intestine, where they molt into larvae 5 (preadults) and finally reach maturity. **Prepatent periods** are species-specific short (about 1.5–3 months), while the **patency** may last 2.5–3 years (Fig. 1).

Name

Greek: *strongylos* = rounded; *oides* = similar.
Latin: *papillosus* = with papillae; *sus* = pig;

rattus = rat; *aves* = birds; *stercoralis* = within feces; *procyon* = racoon; *robustus* = strong.

► [Fuelleborn](#): German parasitologist.

Geographic Distribution/Epidemiology

Worldwide, mostly in countries with warmer climates.

Morphology/Life Cycle

The life cycle of the different species runs as is diagrammatically depicted in Fig. 1. All species which are mostly very tiny with diameters of 0.1 mm or less live in the intestines of their hosts (parthenogenic females)) and outside of the body (free living male and female stages). The free living females reach a length of 0.9 mm, the males 0.7 mm, and thus are considerably shorter than the parthenogenic females in the intestines of their hosts (see Table 1). Eggs are depicted in Fig. 2, parthenogenic females in Fig. 3.

Symptoms of Disease

- (a) **Skin reactions:** Itching at the penetration sites of the infectious larva 3.
- (b) **Lung damages:** Chronic coughing, bronchitis, pneumonia, eosinophilia due to migrating larvae.
- (c) **Abdominal symptoms:** Bloody-slimy diarrheas, loss of weight, hydrothorax, ascites, loss of hair. Heavily infected animals may die especially in cases of a first infection.

Diagnosis

Microscopic demonstration of the typical 45–65 × 25–30 µm sized, larva-containing eggs using concentration methods (= S.A.F.C.) or demonstration of larvae 3 by help of the ► [Baerman](#) technique.

Strongyloides Species of Animals, Fig. 1 Strongyloids. Infection

Percutaneous penetration of infectious, filariforme larvae 3. Oral and galactogenic transmissions of larvae 3 are also possible.

Prophylaxis

Regular quick removal of feces from stables. **Attention:** Larvae 3 remain infectious for up to 10 months in humid surroundings. Use hot steam to clean soil of stables.

Incubation Period

Twelve days after skin penetration, 2–3 weeks after first infection occur intestinal symptoms.

Prepatent Period

Examples:

- *S. papillosus*, *S. westeri*: 9–14 days
- *S. ransomi* (syn. *S. suis*): 6–9 days
- *S. ratti*: 5–7 days
- *S. stercoralis*: 9–19 days
- *S. fuelleborni*: up to 4 weeks

Strongyloides Species of Animals, Fig. 2 Light micrograph of a *Strongyloides* egg containing a larva

Strongyloides Species of Animals, Fig. 3 Light micrograph of a section through an intestine with parthenogenic females

Patency

Months to years.

Therapy

Treatment with benzimidazoles, macrocyclic lactones had been successful as well as application of moxidectin in dogs.

Strongyloides stercoralis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *strongylus* = rounded; *oides* = similar. Latin: *sterx* = terminal end; *stercus* = feces; *stercoralis* = within feces. English: dwarf round worm.

Geographic Distributions/Epidemiology

This worm is found not only in humid and tropic and subtropic regions but also in countries of

South Europe, in mines as well as in zoos (since many monkeys are heavily infected). Several hundred thousands of infections occur worldwide.

Morphology/Life Cycle

S. stercoralis produces two different generations within its life cycle (Fig. 1):

- A free-living generation with males and females
- A parasitic generation, which consists exclusively of females which reproduce themselves parthenogenetically (without fecundation by males)

The parasitic females parasitize inside the mucosa of the upper small intestine and reach a size of 2–2.5 mm × 50 µm. Their anterior end is rounded, while their posterior pole is pointed. These females produce without fecundation eggs, from which still inside the intestine, rhabditiform larvae hatch measuring 350 × 20 µm (Fig. 2). These larvae molt and thus become larvae 2, which are rhabditiform, too, and which can also be found in the feces. They may become males or females of the free-living generation or grow up via one molt to the 500–700 µm long parasitic filariform larvae. If this development occurs still inside the intestine, they may stay inside the intestine. If not, they may enter cutaneously into the skin in the surroundings of the anus (autoinvasion) (Fig. 3).

The first invasion of humans occurs by active penetration of female filariform larvae which have their origin from the free-living generation or which derive from larvae 3 within fecal remnants of humans. Therefore unprotected contact to human feces may be dangerous. Having entered the skin, the larvae migrate into the blood vessels and are transported within the blood stream to the heart and lungs. From there they take their way via the trachea, pharynx, and esophagus to the intestine. About 14–21 days later, the first larvae produced by the parthenogenetic females can be found in the feces of a patient. In cases of constant repeated self-infections especially in humans with

reduced immunity, masses of worms can be accumulated inside the intestine. Thus *S. stercoralis* can be considered as an opportunistic agent of disease.

Symptoms of Disease (Strongyloidiasis)

During the migration through the lungs, bronchitis and/or bronchopneumonia may be introduced. Wandering larvae inside the skin may induce the picture of the so-called creeping eruption on the surface of the skin. Depending on the amount of worms inside the intestine, several differing symptoms may occur. Feces may appear diarrheic, slimy, and bloody and interchange, but also there are phases of obstipation. Abdominal pain may occur as a permanent or interchanging symptom being accompanied by exhaustion and considerable loss of weight. The investigation of the blood often shows eosinophilia, leukocytosis, and anemia. In cases of masses of worms, lethal outcome of such infections may occur – especially in young children or immunocompromised adults.

Diagnosis

The microscopic demonstration of motile larvae in feces and/or fluids obtained from the duodenum is the most significant method. However, since the number of larvae in the feces may be scarce, the so-called Baermann method or the culture techniques according to Harada are recommended for concentration. Immunodiagnostic methods such as ELISA or Western blot have a convincing sensitivity; however, it lacks specificity, since cross-reactions may occur with filariasis or hookworm infections. Furthermore, a second species (*Strongyloides fuelleborni*) in monkeys may also occur in humans.

Infection

Infection occurs by percutaneous invasion of larvae 3 in endemic regions and may also occur in laboratories, if hands are not protected by gloves.

***Strongyloides stercoralis*, Fig. 1** Diagrammatic representation of the life cycle of *Strongyloides stercoralis* (Piekarski 1987). (A) Infection; (B) development outside the body; (C) development inside the intestine. (1a) Parthenogenetic female in the intestine. (1b) Rhabditiform larva (larva 1) in fresh feces. (1c) Filariform larva (larva

3). (2a) Larva 1 (rhabditiform) in fresh feces. (2b) Adult female and male of the free-living generation. (3) Freshly excreted egg by the free-living female. (4) Larva containing egg of the free-living generation. (5) Rhabditiform larva. (6) Infectious filariform larva (= larva 3)

Strongyloides stercoralis,

Fig. 2 Light micrograph of a *Strongyloides* egg containing the larva 1

Strongyloides stercoralis, Fig. 3 Light micrograph of a section of the intestine showing sections of at least two specimens of parthenogenetic females of *Strongyloides* between the protrusions

Thus, in hospitals, special attention must be given to unprotected contact with feces of immunosuppressed persons.

Prophylaxis

Use compact shoes in endemic regions and avoid contact with human feces. Strict use of gloves in laboratories.

Incubation Period

Twelve to eighteen hour after penetration of the larva, skin reactions may occur; after 1 week, lung symptoms can be found, and after 2 weeks, first intestinal symptoms occur.

Prepatent Period

Fourteen to twenty-one days after skin penetration.

Patency

Up to 40 years due to repeated self-infections – proven in cases of World War II soldiers.

Therapy

Drug of first choice is albendazole (400 mg daily for 3 days). Tiabendazole (2×25 mg/kg bodyweight daily for 3 days) is also effective; however, it has side effects. As alternative, mebendazole (2×200 mg daily for 7 days) was also used successfully. Due to the possibility of autoinfections, repetition of the treatment should be done 3 weeks after the first course of

medicamentation. Repeated controls (stool, blood) should be done, too. In cases of persons with a hyperinfection syndrome, albendazole (2 × 400 mg daily for 5–7 days) should be used. Ivermectin proved to be effective, too.

Strongyloidiasis, Man

Strongyloidiasis is produced by ► *Strongyloides stercoralis*, a parasite of humans, dogs, and cats, and occasionally other species, normally from other hosts. Larvae penetrate the skin and give rise to dermatitis at the site of entry. They then migrate either through the lung, where they may cause allergic ► *pneumonia*, or by other pathways to the intestine where they become adults. The females most commonly reach adulthood in the duodenum and upper jejunum and enter the mucosa, to lay eggs. Mucosal inflammation, and later atrophy, leading to malabsorption and emaciation, are the consequence of heavy infections. The larvae, which are soon released from the thin-walled eggs, are shed in the stool. However, some reenter the mucosa or the perianal skin maintaining a ► *chronic infection* which is characterized by fleeting urticarial rashes on the

abdomen, buttocks, thighs, and often perianally. In immunosuppressed hosts this autoinfection can lead to a marked increase in tissue invasion by larvae and of adult females in the gut (► *Pathology*, Fig. 2F), which may contribute to a fatal outcome.

Main clinical symptoms: Bronchitis, bronchopneumonia, ► *diarrhoea*, loss of weight, ► *eosinophilia*, ► *anaemia*, death.

Incubation period: Skin: 12–18 hours, lung: 1 week, intestine: 2 weeks.

Prepatent period: 14–21 days.

Patent period: 40 years (due to repeated autoinfections).

Diagnosis: Microscopic determination of larvae in faeces or duodenal fluid, ► *Serology*.

Prophylaxis: Use solid shoes in endemic regions and avoid human faeces.

Therapy: Treatment see ► *Nematocidal Drugs, Man*.

Strongyloidosis, Animals

Pathology

Ruminants

► *Strongyloides papillosus* occurs in cattle, sheep, and goats. This nematode lives in tunnels within the epithelium of the villi of the anterior part of the small intestine. Severe infections cause villous atrophy, with a loss of plasma proteins and a reduced activity of several enzymes (alkaline phosphatase, lactase, saccharase and maltase). Clinical outbreaks principally affect young suckling animals. Signs include ► *anorexia*, loss of weight, ► *diarrhoea* (rarely haemorrhagic), ► *dehydration*, slight to moderate ► *anaemia*. Severe infections may be fatal. Studies in Japan demonstrated that *S. papillosus* could cause sudden death in calves.

Horses

The only species in the small intestine of horses is *Strongyloides westeri* (► *Alimentary System*

Diseases, Ruminants). Clinical outbreaks principally affect young suckling foals. Signs include anorexia, loss of weight, coughing, diarrhoea (rarely haemorrhagic), dehydration, slight to moderate anaemia. Severe infections may be fatal.

Carnivores

► *Strongyloides stercoralis* occurs in dogs. Though not common, infection in young animals may have severe consequences. There is enteritis with erosion of the mucosa of the small intestine, and haemorrhages. Bloody diarrhoea occurs in heavy infections. Dehydration develops rapidly, and death may occur.

Swine

Strongyloidosis caused by *Strongyloides ransomi* occurs in swine. Clinical outbreaks principally affect piglets. Signs include anorexia, loss of weight, diarrhoea (rarely haemorrhagic), dehydration, slight to moderate anaemia. Severe infections may be fatal.

Therapy

► **Nematocidal Drugs, Animals.**

Strongylus Species of Equids

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *strongylus* = rounded; Latin: *edentatus* = without teeth; *vulgaris* = common, normal; *equinus* = belonging to horses; *asinus* = donkey

Geographic Distribution/Epidemiology

Worldwide; however, *S. asini* was only recorded in Africa, Asia, and South America.

Morphology/Life Cycle

This group encloses four main species:

- (a) *Strongylus asini*: Females, 3–4.2 cm; males, 1.8–3.3 cm; they possess two ear-like teeth at the base of the mouth capsule. Eggs, 75 × 45 µm.
- (b) *Strongylus edentatus*: Females, 2.8–4.4 cm; males, 1.9–2.8 cm. No teeth at the base of the mouth capsule (Fig. 1). Eggs, 64 – 99 × 40 – 57 µm.
- (c) *Strongylus equinus*: Females, 3.5–5 cm; males, 2.4–3.5 cm. Two subventral teeth and one dorsal tooth (with a divided tip) at the base of the mouth capsule (Fig. 1). Eggs, 70 – 90 × 40 – 55 µm.
- (d) *Strongylus vulgaris*: Females, 1.3–2.5 cm; males, 1–1.9 cm; two ear-like teeth at the base of the mouth capsule (Figs. 1 and 2). Eggs, 74 – 95 × 36 – 58 µm.

These rather stiff worms are firmly attached at the intestinal wall with the help of their large hollow mouth capsules, which help to suck blood. The eggs are excreted within the host's feces. The larva 1 hatches from the egg and develops the body into the infectious larva 3, which creeps in the morning and evening hours at the tips of grass blades, where they may become ingested by their hosts. Inside these hosts, a species-specific wandering phase occurs.

- (a) *S. equinus*: After desheathing, the larva 3 enters via the mucosa into the submucosal region of the cecum and colon and introduces there the formation of nodules. After about 10–11 days, the larva 4 is formed, which enters the body cavity, and after further 6–8 weeks, penetrates into the liver. Afterward, it reenters the body cavity, where the formation (by desheathing) of the preadult stages occurs, which enter again the intestinal lumen and reach maturity there.
- (b) *S. edentatus*: The larvae 3 reach the liver via the vena portae, where after 11–18 days, the formation of the larva 4 is proceeded. These larvae 4 live for about 9 weeks in the liver

Strongylus Species of Equids, Fig. 1 Diagrammatic representation of the anterior ends of three *Strongylus* species. (a) *S. equinus*; (b) *S. edentatus*; (c) *S. vulgaris*.

Strongylus Species of Equids, Fig. 2 Light micrograph of a *Strongylus* egg

tissues. Afterward, they reach via the peritoneal wall on the right abdominal region of the body, where hemorrhagic nodules of 1–5 cm in diameter are formed, within which the molt into the preadult stages occurs. These preadults penetrate into the lumen of the cecum and colon, where they reach maturity.

- (c) *Strongylus vulgaris*: The larva 3 enters the intestinal wall, where the molt into larva 4 occurs. These stages enter within 8 days the intima of arterioles of the submucosa of the small intestine and introduce there thrombic formations and aneurysms. About 45 p.i., the larva 4 migrates to the submucosa of the cecum and colon and molts there into the preadult stage. After reentering the intestinal lumen, maturity is reached.

Symptoms of Disease

- (a) **Damages due to adults:** Anemia, edemas, loss of appetite and weight, diarrheas, and weakness

Strongylus Species of Equids, Table 1 Effective nematocidal compounds for horses

Chemical short name	Dose (mg/kg p.o.)	Large strongylids, immature	Large strongylids, mature	Small strongylids, immature/mature	Small strongylids, benzimidazole resistant
Pyrantel pamoate	19.0		+++	+++	+++
Cambendazole	20.0		+++	+++	
Dichlorvos	30–60 ^a	?	+++	+++	
Ivermectin	0.2	+++	+++	+++	+++
Parbendazole	2 × 2.5		+++	+++	+++
Fenbendazole	7.5	+++ ^b	+++	+++

Tiabendazole	50.0	+++ ^c	+++	+++	
Oxibendazole	10.0		+++	+++	+++

^aDepending on age, body weight, animal species (horse, donkey)

^bAccording to literature: 5 days, 7.5–10 mg/kg p.o.

^cAccording to literature: 2 days, 440 mg/kg p.o.

- (b) **Damages due to larvae:** Bleeding of the colon mucosa, fever, leukocytosis, aneurysms, emboli, local endarteritis chronica, thrombosis, chronic limp (e.g., in cases of infections with *S. vulgaris*)
- (c) **Chemoprophylaxis:** Regular treatment with anthelmintics reduces risk of excretion of eggs.

Incubation Period

7–15 days.

Diagnosis

Microscopical determination of the eggs which are excreted in a multicellular stage. See ► [flotation](#); S.A.F.C. Species determination; larval culture.

Prepatent Period

S. edentatus, 10–11 months; *S. equinus*, 8–10 months; *S. vulgaris*, 5–7 months.

Infection

Oral uptake of free-living larvae 3 within contaminated food or with grass. **Attention:** Larvae remain infectious for 2 months in hay and may even remain overwinter on grass.

Patency

1–2 years.

Prophylaxis

- (a) **Hygienic measurements in stables:** Quick removal of feces and disinfection of floors.
- (b) **Pasture:** Alternating use of meadows by horses and cattle.

Therapy

For treatment of the *Strongylus* species, a broad spectrum of anthelmintics is available. However, it is very important that also the immature stages are killed. It is recommended (at least in Europe) to use anthelmintic products according to the following scheme:

Treatment every 2 months with a product of the following groups (Table 1):

- (a) **Group:** Compound with effects on nematodes and → *Gasterophilus* flies
- (b) **Group:** Broad spectrum anthelmintics with efficacy in adult and immature nematodes (strongylids, ascarids, oxyurids)
- (c) **Group:** Anthelmintics, which do not belong to the benzimidazoles, in order to avoid development of resistances in small strongylids (e.g., macrocyclic lactones)

Strongylus vulgaris

Name

Greek: *strongylos* = rounded.

Classification

Species of the nematode family Strongylidae.

Life Cycle

The species of the genus *Strongylus* (*S. vulgaris*, *S. equinus*, *S. edentatus*, *S. asini*) are 1–5 cm long, yellowish-brown roundworms with a buccal capsule (Figs. 1 and 2). They are found worldwide in the caeca and colon of equids. The **prepatent periods** are long (6.5–11 months), since the larva 3 starts a parental wandering (and rest) after being taken up with the food.

Sulfadoxine Pyrimethamine Resistance

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This compound is used in Africa for intermittent preventive therapy in pregnant women (IPT_p) and infants (IPT_i). The resistance of some *Plasmodium falciparum* strains against a treatment with sulfadoxine pyrimethamine is due to the fact that resistant strains show a mutation in the genes *Pfdhfr* (*P. falciparum* dihydrofolate reductase) and *Pfdhps* (*P. falciparum* dihydropteroate synthase). These apparently progressing resistances endanger any mass treatment. In three foci of East Africa the populations are already fully resistant.

Summer Bleeding

Symptom of disease due to infections with ► [Parafilaria](#) spp., which form skin nodules. These nodules break off due to UV-light leading to skin bleeding. The microfilariae are then found

in the wound and become transmitted by ► [Haematobia](#) flies.

Summer Influenza

Disease (flu) due to the Tahyna virus which is (occasionally) transmitted during bites of blood-sucking ► [mosquitoes](#) in the European summer.

Summer Ostertagiosis

Infection due to ► [Ostertagia](#), see also ► [Nematodes](#).

Sunken Epithelium

The inner ► [cell membrane](#) of the syncytical ► [tegument](#) of ► [Platyhelminthes](#) is connected to finger-like protrusions of parenchymal cells (► [Platyhelminthes](#), Figs. 11 and 19), the cell body (cyton) of which is situated below the circular and longitudinal muscle bundles. These connections, which pass the basal lamina, led in earlier light microscopic studies to descriptions such as “sunken epithelium” for the body wall of platyhelminths (► [Platyhelminthes](#)/ ► [Integument](#)).

Superinfection

Occurrence of a second infection besides an existing primary one.

Suprapopulation

This term describes all individuals (including all developmental stages) in all hosts in a given ecosystem.

Surface Coat

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Synonyms

Glycocalyx (Apicomplexa/Surface Coat).

General Information

Surface coats are present both in protozoan and in helminthic endoparasites. In general, the plasma membrane of cells is strikingly asymmetric, its outer and inner layers are clearly delineated, and the polypeptides on each surface are distinct. Glycolipids, glycoproteins, and glycosphingolipids

are present only on the external surface. The peripheral layer is rich in carbohydrate and is called the glycocalyx, or surface coat. The thickness of this layer varies with the species and with the developmental stage of the organism (Fig. 1, ► [Pellicle](#), Fig. 3A). Not only is the surface coat composed of glycoproteins and glycolipids, but various glycoproteins and proteoglycans (acid mucopolysaccharides) may also be adsorbed to it (for more details see ► [Apicomplexa](#)/► [Surface Coat](#)). The surface coat may be a rather delicate coating, a mass of delicate filaments, or a thick mat, and it comprises 10 % of the cell protein. Whatever its structure, the surface coat has several functions in the life of the organism: (1) it acts as a mechanical or chemical barrier; (2) it plays a role in recognition and adhesion to other cells; (3) it contains enzymes that act on substances in the environment; and (4) it contains molecules that can act as antigens and thus plays an important role in the initiation of immunological processes. The surface coat may change its composition as the parasite develops from stage to stage.

Surface Coat, Fig. 1 TEMs of the surface coat. (a) ► *Toxoplasma gondii*; the ► *zoite* within a host cell vacuole (PV) shows a slight positive Thiéry reaction along its surface (arrow). Note the presence of amylopectin (A) granules in the parasite and of glycogen (G) in the host cell. C, ► *conoid*; MI, mitochondrion; N, nucleus; NH,

nucleus of the host cell; R, rhoptry ($\times 7,000$). (b) ► *Trypanosoma vivax*; cross-section through a trypomastigote stage showing the discharge of a thick surface coat (arrow). AX ► *axoneme*, F flagellum, PR ► *paraxial rod*, ST ► *subpellicular microtubule* ($\times 25,000$)

What has been originally described as a surface coat on parasitic ► [Protozoa](#) has further been shown to be the electron microscopic image of surface glycoproteins or glycolipids sharing a common original feature: all the molecules are anchored in the plasma membrane by a ► [glycosylphosphatidylinositol](#) (GPI) moiety. This type of anchor had been discovered in trypanosomes, before being found in many eucaryotic cells, where it often coexists with transmembrane proteins. In parasitic protozoa, the GPI anchor is by far the most important type of plasmalemmal protein.

The surface coat that fulfills its tasks in defending the cell against environmental influences while covering “normal” and parasitic cells is thought to be the ancestor of all cuticular systems of the whole animal and plant world. Apparently during evolution, the glycocalyx, while situated between body and/or cell protrusions (e.g., ► [microvilli](#), protuberances), became fortified by enclosing fibers of collagen, ► [chitin](#), cellulose, and/or calcium carbonate components, etc. Thus, the original protection system received a second function, i.e., the preservation of the body shape as a system belonging to the exoskeleton. However, the uptake of nutrients through this increasing outer surface remained possible by using a variety of mechanisms and carrier systems. Thus, for example, schistosomes are able to take in huge amounts of glucose through their surface membranes and ► [nematodes](#) may become hidden by several drugs due to their cuticular uptake, too (► [Platyhelminthes](#)/► [Integument](#), ► [Nematodes](#)/► [Surface Coat](#), [Acanthocephala](#)/Surface Coat).

Antigenic Variation

Many parasitic Protozoa, in particular the blood stages of the trypanosomes, have developed the ability to change their surface coat by ► [antigenic variation](#) (Fig. 2). This may be achieved by selective activation of different genes at different times. Organisms of the *Trypanosoma brucei* group have

up to 1,000 genes that may become activated during the production of variant surface glycoproteins (VSGs). This selective activation results in changes in the variable antigen types (VATs) displayed and hinders the host defense against these blood-inhabiting flagellates. Blood stages of ► [Plasmodium](#) and piroplasmic species may also display variant antigen types, but there are fewer variants than those displayed by trypanosomes. The action of these genes results in antigenic variation and the production of immunologically different strains of Protozoa; this explains why most antiprotozoal vaccines provide only limited protection, restricted to certain localities. The development of potent vaccines against protozoan parasites depends on the discovery of species-specific antigens with invariant epitopes that are accessible to the immune system during the parasite's life (Fig. 2). In addition, they must be essential to the parasite's survival, possibly playing an important role in cell recognition, adhesion, ► [immune evasion](#), metabolism, and/or cell invasion. Whether such antigens exist in significant amounts, in various developmental stages of many parasitic stages, remains to be determined.

Inside their evertbrate vector the parasitic stages develop a surface coat, too. Thus the trypanosomatids shed their VSG-coat when they reach their vector's intestine and replace it by a coat called ► [Procyclin](#) or ► [PARP](#) (Procyclic Acidic Repetitive Protein) which consists of 400–500 aminoacids linked (like the VSGs) to the parasite's cell membrane by a GPI-anchor (► [Glycosylphosphatidylinositols](#)). However, this PARP-coat, which is regulated by the activity of eight genes, shows apparently no variation and is not preserved in bloodstream forms. As was recently shown, both PARP- and VSG-genes become transcribed by RNA-polymerase I, which normally only transcribes the ribosomal RNAs and which does not add a cap to the 5'-end of the RNA. This peculiar occurrence – probably made possible because of *trans*-splicing – is perhaps expression of the rather early divergence of the trypanosomatids from the eukaryotic lineage.

Surface Coat, Fig. 2 Diagrammatic representation of a cell, the surface of which is covered by a surface coat consisting of variant surface glycoproteins (► *VSG*) and a few (ratio 1:100) invariant surface proteins (*ISG*). Both are differently anchored in the membrane. The transmembranous proteins, glycolipids, and sphingolipids,

etc. are not drawn. *GPI* glycosulphosphatidylinositol-anchor, *H* α-helical anchor, *ISG* invariant surface glycoprotein, *PHI* hydrophilic region of the ► cell membrane, *PHO* hydrophobic region of the cell membrane, *VSG* variant (dimeric) surface protein

Surra

Trypanosoma evansi (syn. *T. equinum*) has a wide range of hosts and is pathogenic to most domestic animals (► [Trypanosomiasis, Animals](#)). Camels, horses, dogs, and Asian elephants are highly susceptible. The infection in horses (called surra) and dogs is severe and probably uniformly fatal in the absence of adequate treatment. Cattle are mildly affected and act as reservoir.

Therapy

► [Trypanocidal Drugs, Animals](#).

Surra-Syndrome

Disease of ruminants due to an infection with *Trypanosoma brucei evansi*, named in honour of its discoverer (G. H. Evans), who described the parasite in 1880 in India. The name comes from Hindi language: *surra* = foul, degenerating.

Survival Strategies, Protozoa

Intracellular protozoans have developed different strategies to survive attacks of the host defense systems. Examples are:

1. *Leishmania* spp. invade by receptor-mediated phagocytosis, are placed inside phagolysosomes, become protected inside by lipophosphoglycan.
2. *Trypanosoma cruzi* tissue stages enter actively their host cells, lay immediately in the cytoplasm, and are protected there by a protein (C 9 cross-reactive protein, TcTox trans-sialidase).
3. *Toxoplasma gondii* tachyzoites enter actively, are situated in a fusion-resistant parasitophorous vacuole and are protected there by the excreted proteins of micronemes, rhoptries, and dense granules.

Suture

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Name

Latin: *sutura* = suture.

This term describes the line where wings of originally motile wings of insects have fused.

Swarmer

Infectious stage of some ciliates
 ► *Ichthyophthirius multifiliis* and
 ► *Cryptocaryon irritans*; they are formed inside
 cysts at the bottom of their habitat (e.g.,
 pond, lake).

Swarming

Males of several ► [mosquitoes](#) form swarms in the evening twilight and this attracts females in order to mate.

Sweating Sickness

This is an acute toxicosis of cattle, sheep, goats, pigs due to injection of immunogenic toxins in the saliva of the tick *Hyalomma truncatum* in South Africa and India.

Symptoms

Name-giving sweating, lacrimation, salivation, acute dermatitis, stomatitis, and secondary infections. ► [Tick Bites: Effects in Animals](#).

Sweet Itch

Disease (also named: summer wounds) in horses due to bites of midges (► [Ceratopogonidae](#)). In horses these *Culicoides*-spp. bite along the margin of the eyes, at the belly and feet. Their aggressive saliva introduces pain and intensive allergic reactions in the skin.

Swim Bladder Disease

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Disease due to an infection with microsporidian spores (e.g., *Sphaerospora*, *Tetracapsuloides*) often seen in carps and salmonids.

Swimmer's Itch

Christian Selbach and Bernd Sures
Aquatic Ecology, University of Duisburg-Essen,
Essen, Germany

Synonyms

Cercarial dermatitis

General Information

Swimmer's itch is an inflammatory skin infection caused by the free-swimming larvae, the cercariae, of certain digenean trematodes of the family Schistosomatidae. Except in Antarctica, the disease occurs worldwide and is regarded as a reemerging disease in Europe and North America that has received both public and academic interest due to the potential severity of infections and the possible economic impact on regions with a focus on recreational water activities (Soldánová et al. 2013). In Europe and North America, the most important causative agents of swimmer's itch are bird schistosomes of the genus *Trichobilharzia* with a two-host life cycle that requires both aquatic snails and waterfowl (see Horák et al. 2002 for a comprehensive review of *Trichobilharzia* spp.). Mammalian schistosomes of the genus *Schistosoma* can also cause cercarial dermatitis when infecting humans but are of more serious medical interest as causative agents of schistosomiasis or bilharziasis.

Life Cycle

Waterfowl serve as a definitive or final host in which the schistosomes reach sexual maturity, mate, and produce eggs (Fig. 1). Depending on the species-specific location within the final host,

eggs are either released via the host's feces where the miracidia hatch in the water (visceral schistosomes) or are deposited in the bird's nasal mucosa where the miracidia hatch and leave the host upon contact with water (nasal schistosomes). The free-swimming miracidia act as a first dispersive stage and actively penetrate a suitable molluscan intermediate host where asexual reproduction via mother and daughter sporocysts occurs. The sporocysts produce numerous free-swimming larvae, the furcocercous cercariae (Fig. 2), that leave the snail host to find and infect a potential bird host and thus close the parasite's life cycle.

The highest cercarial emission is synchronized with final host activity and occurs during the morning hours with several hundred to several thousand cercariae released per snail and day (see Fig. 3 and Video 1).

Like the miracidia, the cercariae do not take up food and have a limited lifespan of one to three days, depending on water temperature. However, infection success of the larvae decreases during the lifetime of the cercariae, resulting in highest infectivity immediately after release from the snail host. In order to maximize infection success, the cercariae show a positive phototactic and a negative geotactic orientation and collect at the water surface where chances of a host encounter are highest. Stimulated by shadow, water turbulence, and chemical signals (fatty acids, ceramides, cholesterol), the cercariae actively seek out and penetrate into potential hosts (Haas 1992). Upon penetration of the bird host's leg, the cercaria transforms into a juvenile worm, the schistosomula, by shedding its tail and migrates to its final location within the host, either via the circulatory system (visceral schistosomes) or through the peripheral nerves and central nervous system (nasal schistosomes, e.g., *Trichobilharzia regenti*).

Prevalence in Snails and Birds

Until now, six genera of schistosomes have been described from aquatic birds, mostly of the order Anseriformes (ducks, geese, and swans) as definitive hosts in Europe: *Allobilharzia*, *Bilharziella*,

Electronic supplementary material: The online version of this chapter (doi:► [10.1007/978-3-662-43978-4_3501](https://doi.org/10.1007/978-3-662-43978-4_3501)) contains supplementary material, which is available to authorized users.

Swimmer's Itch,

Fig. 1 Generalized life cycle of a bird schistosome. Swimmer's itch occurs when cercariae accidentally penetrate human skin where they can cause an allergic reaction (Reprinted from Soldánová et al. 2013, with permission from Elsevier)

**Swimmer's Itch,**

Fig. 2 *Trichobilharzia franki* cercaria

Dendritobilharzia, *Gigantobilharzia*, and *Trichobilharzia*. From the marine environment, species of the genus *Ornithobilharzia* occur in charadriiform and procellariiform birds and marine gastropods. However, in ongoing studies on larval stages in the snail hosts, several previously undescribed species are recognized as a result of the application of molecular markers for

species identification. Snail hosts known to harbor most of the bird schistosome diversity in Europe are freshwater pulmonates of the families Lymnaeidae and Planorbidae with *Lymnaea stagnalis* and *Radix* spp. as the most frequently and widely distributed intermediate hosts for the most important and common bird schistosomes of the genus *Trichobilharzia*. Infection rates in snails

may vary annually and/or seasonally with increases in the summer months following the occurrence and age structure of snail populations. Prevalence of bird schistosomes in snails in Europe show generally low levels (mostly ranging from 0.05 % to 5.0 %) compared to infection rates in birds (up to 74.5 %) with occasionally occurring prevalences of up to 40 % in snails, especially in eutrophic environments. Although often at the centre of research attention due to their relevance as pathogens, bird schistosomes usually only constitute a small part of the rich trematode fauna found in aquatic ecosystems (e.g., Soldanova et al. 2010).

Human Infection

Swimmer's itch occurs when bird schistosome cercariae infect humans as accidental hosts in which the parasites cannot successfully complete their life cycle but die in the skin where they can cause allergic inflammatory reactions (Fig. 4). Although usually not harmful, swimmer's itch is highly unpleasant due to intense itching of the infections for up to several days.

Primary infections in unsensitized individuals usually show mild or no skin reactions and often go unnoticed, whereas repeated exposure to the parasites lead to a host sensitization and inflammatory reactions caused by the human immune system in response to the entrapped cercariae. Cercarial penetration into the skin is accompanied by a primary itching and the development of transitory maculae that can be followed by intensely itching (secondary itching) papulae that, depending on sensitivity of the infected host, usually disappear after 10 days (Horák et al. 2002). Strong infections in repeatedly sensitized persons can lead to related symptoms, such as lymph node swelling and fever (Horák and Kolářová 2001). Furthermore, transformed schistosomula may be able to escape the immune system in unsensitized mammals and migrate in the body where they die. Likewise, neuropathogenic bird schistosomes, such as *Trichobilharzia regenti*, have shown to be able to migrate through the central nervous system of mammals where they present a risk of

Swimmer's Itch, Fig. 4 Severe case of swimmer's itch (Reprinted from Soldánová et al. 2013, with permission from Elsevier)

potential neurologic disorders (e.g., leg paralysis in laboratory mice). As it is still uncertain whether these symptoms can occur in humans, these parasites require further attention (Horák and Kolářová 2001; Horák et al. 2002). Although unpleasant, the manifestation of swimmer's itch can therefore be regarded as beneficial, as it indicates an effective immune response of the body against the invading schistosomes and the destruction of the parasites entrapped in the skin (Horák and Kolářová 2011).

Risk Factors

A wide variety of aspects, ranging from ecological and environmental factors such as eutrophication,

temperature, or aquatic vegetation to personal behavior, have an effect on the likelihood and severity of an infection with bird schistosomes and the development of swimmer's itch. Many of these factors are connected (e.g., season and aquatic vegetation), making a monocausal risk assessment impossible but highlighting the need to take the interacting variety of biotic and abiotic factors into consideration, especially when looking at parasites with a complex life cycle that involves several hosts and transmission stages. Especially factors such as climate change or eutrophication of water bodies have far-reaching ecological effects that enhance the parasites' occurrence and spread to new areas, thereby increasing the chance of infections in humans. Table 1 provides an overview of the most important risk factors of swimmer's itch.

Preventive Measures

Based on the parasites' biology and ecology, a wide range of possible preventive measures aiming at the disruption of the life cycle at various stages, ranging from pest control of final or intermediate hosts to direct control of the free-swimming dispersive stages, have been suggested and tested with varying success and ecological impact (reviewed in Soldánová et al. 2013). Personal preventive measures and changes in bathing behavior based on the potential risk factors (see Table 1) can help to reduce the risk of an infection. Avoiding swimming during the morning hours when cercarial emission is highest and shallow waters with aquatic vegetation has been suggested to reduce the chance of encountering the parasites. However, these personal preventive measures can only help to reduce the risk of an infection but can never provide absolute protection, since snail and trematode occurrence cannot be restricted to regional clusters or temporal windows. Cream formations that inhibit cercarial penetration into the skin have proven to be effective but need to be applied before bathing.

Swimmer's Itch, Table 1 Most important swimmer's itch risk factors and potential preventive measurements (Modified from Soldánová et al. 2013, see references therein)

Risk factor		Effect	Preventive measurements
Personal factors and behavior	History of swimmer's itch	Individual history of swimmer's itch plays an important role, since repeated exposure and infection correspond with a higher chance of contracting cercarial dermatitis and severity of infection due to host sensitization. Primary infections usually show mild or no skin reactions	Cream formulations that inhibit cercarial penetration Bathing restrictions
	Age	Significantly higher risks of infection among children younger than 15 years are reported, most likely due to age-related bathing habits, i.e., children spending more time in shallow, warm water where snails and parasites accumulate. However, evidence is inconclusive since some studies observed no significant effect of the age factor	
	Bathing activity	Bathing behavior has a significant influence on the chances of encountering bird schistosome cercariae. People engaged in immersed activities (swimming, wading) are at higher risk than those merely engaged in surface activities, such as surfing, water skiing, or boating, due to higher exposure to cercariae	
	Bathing time	The amount of time spent in water positively correlates with the risk and severity of an infection, as the longer exposure allows more possible cercarial penetrations	
	Frequency of visits	The frequency of visits to the water body corresponds with higher incidence of swimmer's itch, due to increased chances of encountering the parasites. Contrastingly, negative associations between days of exposure and disease severity were found, which probably indicates that sensitized people with a known history of swimmer's itch tend to reduce or avoid recreational use of potentially infested waters	
Bathing locality	Shallow waters/surface water	Spending time in shallow water is associated with high infection risks because snails accumulate in shallow waters where cercarial production is further enhanced by high water temperatures in summer. However, suitable hosts can also occur at greater depths, and the risk of swimmer's itch can, therefore, not be restricted to shallow areas, although risk of an infection is highest there. Bird schistosome cercariae become concentrated at the water surface. Therefore, contact with surface water at sites with abundant snail communities can be considered a risk factor	Avoiding shallow waters where snails can accumulate Clearing bathing sites of snail hosts by mechanical removal, habitat disturbance, biological control, or molluscicides (often at high ecological costs)
	Aquatic vegetation	Rich aquatic vegetation is often considered an indicator of potential high-risk sites, as it provides ideal conditions for abundant snail communities. However, suitable snail hosts can also occur in areas free of vegetation (e.g., on stones or sediment)	

(continued)

Swimmer's Itch, Table 1 (continued)

Risk factor		Effect	Preventive measurements
Time	Season	Season shows a significant association with human infections, as most cases occur during warm summer months with prolonged daylight hours and increased water temperatures when prevalences in snails are highest and both cercarial emergence and human bathing activities peak	Avoiding morning hours when cercarial emission is highest
	Time of day	Both probability and severity of infection are highest during the morning hours when cercarial emergence peaks. Infectivity of released free-swimming cercariae declines with time, and the free-swimming larval stages are subject to predation by a wide variety of animals, probably further reducing the risk of human infection as the day progresses	
Weather	Air temperature	High air temperatures correspond with high infection risks, probably due to increased bathing activity (i.e., more time spent in water) and higher cercarial emergence rates	
	Water temperature	High water temperature is considered a risk factor, as high abundances of infected snails can often be found in warm waters and cercarial emergence is enhanced	
	Sunshine	Long periods of sunshine increase the number of recorded outbreaks of swimmer's itch due to increased bathing activities and elevated cercarial emission on sunny days, especially following overcast periods	
	Wind and water movement	Onshore winds and water currents correspond with increased infection risks, as they can transport cercariae that become concentrated in the surface water layers toward bathing sites. Clouds of cercariae may be transported by winds and currents for several kilometers. Infections can, therefore, also occur in areas seemingly devoid of snails	
Other factors	Eutrophication	An ecological key factor that triggers a cascade of factors (high host abundances and high prevalence) ultimately leading to an increased risk of human infections	
	Global warming	Increased risk of swimmer's itch expected, as overwintering migratory birds in central Europe allow a longer host–parasite transmission window, leading to higher parasite prevalence and higher densities of cercariae. Higher temperatures enhance cercarial production

mother's "milk glands", while the *Wolbachia*-stages are included into the eggs.

Swollen Belly Syndrome

Symptom/syndrome in children due to infection with *Strongyloides fuelleborni* (protein-losing-enteropathy, respiratory distress, diarrhea); in dogs ► *Toxocara canis* Toxocariasis (► *Toxocara*, Fig. 1).

Sylvatic Cycle

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This is an infection cycle between parasites or other agents of disease on one side and hosts on the other, which does not include humans, but runs independently far from human settlements. Examples are the ► *Chagas disease* due to ► *T. cruzi* and raptor bugs when infection occurs not in human habitats but exclusively between vertebrate hosts and bugs in the wilderness. Another example for a sylvatic cycle is the transmission between dengue fever viruses and mosquitoes as vectors not in towns, but among reserve hosts in forests.

Symbionts in Tsetse Flies

There are two members of the enterobacterian type found in the gut. The obligate mutualist *Wigglesworthia* and the facultative secondary (= S =) symbiont *Sodalis*. A third type is the parasite microbe *Wolbachia pipientis* which is related to the λ -proteobacteria. The gut microbes are transmitted to the progeny of the flies via the

Symbiosis

Name

From Greek: *symbiosis* = living together.

This term describes the cohabitation of 2 different types of organisms, both benefiting from this way of living. For example, see the occurrence of ► *Wolbachia*-bacteria in insects or filariid worms.

Sympatric Distribution

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term was created to describe the phenomenon when two species of the same group occur in the same geographic area and thus regularly encounter each other.

Sympatry

From Greek: *sym*, *syn* s= together; Latin: *patria* = homeland. Occurrence of 2 species within the same geographic zone or the same habitat.

Symphoromyia

Genus of ► *snipe flies*.

Synanthropic Cycle

Life cycle of parasites involving humans at essential positions.

Synapomorphy

A shared derived character state. ► [Phylogeny](#).

Synaptonemal Complex

Attachment zone of pairing ► [chromosomes](#); this region appears in electron microscopy as a bandlike, 100 nm broad, striated zone, see ► [Cestodes/Reproduction](#), ► [Platyhelminthes](#).

Synchronicity

Phenomenon found in all human malarial parasites, that after a short phase of adaptation the growing of schizonts, the formation of merozoites, and the resulting rupture of the red blood cells occur at the same time in all infected red blood cells. It has been suggested the paroxysms of fever sharpen the level of synchronicity. Furthermore the host's circadian rhythm is also a determining factor. Altogether synchronicity represents an adaptation of the parasites to optimize the transmission by night-biting mosquitoes (► [Anopheles](#) spp.).

Syncytium

Mass of ► [cytoplasm](#) containing many nuclei enclosed in a single continuous plasma membrane (► [Plasmalemma](#), ► [Tegument](#), ► [Platyhelminthes/Integument](#)).

Synergists

Important Compound

Piperonylbutoxide (PBO), n-octyl bicycloheptene dicarboximide (MGK 264).

General Information

Synergists usually enhance the efficacy of an ► [arthropodicidal drug](#) without displaying toxic effects by themselves. In most cases synergists are thought to act by inhibiting metabolism of a given drug and in this context can be used at least, sometimes to prolong the activity of a compound in resistant parasite strains. PBO, one of the most frequently used synergists, inhibits cytochrome P-450 microsomal monooxygenases, and is used together with DEET (► [Repellents](#)) and pyrethrins (► [Arthropodicidal Drugs/Pyrethroids and DDT](#)) to control ► [lice](#) and biting ► [midges](#) on companion animals.

Syngamus Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek – *syn* = together, *gamos* = fusion.
 Latin – *trachea* = trachea, breathing tube.
 English – grape worm.

Geographic Distribution/Epidemiology

Worldwide in many bird and mammal species; in cases of farmed birds, often high prevalence rates have been observed.

Syngamus Species, Fig. 1 Life cycles of nematodes with facultative or obligate intermediate hosts. (a) *Stephanurus dentatus* adults (male 23 cm, female 34.5 cm) live in cysts of kidneys of swine (final host). (b) *Porrocaecum ensicaudatum* (female 45 cm) lives as adults in the small intestine of

blackbirds. (c) *Syngamus trachea* (redworm, gapeworm); males (6 mm) and females (20 mm) suck blood in the trachea of poultry and are permanently attached to each other, thus giving a Y shape to the pair. 1 Eggs are mainly passed in urine (*S. dentatus*) or feces (other species) of final hosts. 2 On the

Morphology/Life Cycle

Two species of the genus *Syngamus* are common and most important:

- (a) *Syngamus trachea* (Fig. 1). The adults of this so-called red tracheal worm measure 8 mm (males) in length and 20 mm (females), respectively, which live in permanent copulation attached at the tracheal wall, thus offering a Y-shaped aspect. Both sexes suck constantly blood at different places and thus appear reddish in shape. The females excrete the thick-walled 70–100 $\mu\text{m} \times 45\text{--}50 \mu\text{m}$ -sized eggs in an unembryonated stage (containing a morula of about 16 cells). The egg shell is characterized by thickenings at both poles (Fig. 1). The larva 3 is formed inside the egg shell within 1–2 weeks. If snails, earthworms, insects, or their larvae ingest such eggs, they may become accumulated there (larvae 3 may hatch, too). If birds ingest larvae 3 containing eggs or swallow such infested intermediate hosts, the larvae penetrate into the wall or directly into the body cavity. They reach the lung via the bloodstream or directly by entering the lung from the body cavity. From there they migrate into the lumen of the trachea, where they copulate and reach maturity within 1 week (Fig. 2). However, another week is needed until the first eggs are excreted.
- (b) *Syngamus* (syn. *Cyathostoma*) *bronchialis*. This species parasitizes in the trachea and bronchioles of geese, ducks, and free-living birds. The males reach a length of about 6 mm, while the females are considerably longer (up to 3 cm). The adults do not live in permanent copulation, and the males appear whitish, while the females appear even dark

red due to their permanent blood sucking. The further development is similar to that of *S. trachea* (Fig. 1).

- (c) *Syngamus* (syn. *Mammomonogamus*) *laryngeus* occurs in the larynx of cattle and buffaloes in Asia, South and Central America, Sri Lanka, and the Philippines.
- (d) *Syngamus* (syn. *Mammomonogamus*) *nasicola* is found in the nose cavities of ruminants in Africa and South and Central America.
- (e) *Mammomonogamus* (syn. *Syngamus*) species of animals are also found in cats and in humans.

Symptoms of Disease (Syngamosis)

Especially young animals may become severely affected and show intense coughing, breathing problems (dyspnea seen by open mouth), tracheitis, apathia, loss of weight, anemia, death due to weakness, or suffocation. Adult animals mostly show only lower-graded symptoms.

Diagnosis

Microscopical inspection of the typical eggs (Fig. 1); (see nematode eggs of birds) after use of concentration methods (flotation, S.A.F.C.). Occurrence of adult worms in vomited material.

Infection

Oral uptake of infectious larva 3 containing eggs, larvae 3 or egg containing intermediate hosts such as earthworms, insects, snails, etc.

Syngamus Species, Fig. 1 (continued) soil, the eggs embryonate, leading to a first-stage larva (L1). In *S. trachea* development proceeds until the L3 is formed inside the egg, whereas in *S. dentatus* the L1 may leave the egg (2.1–2.2). Intermediate hosts may ingest the eggs (in *P. caudatum* it is obligatory), thus initiating the development of infectious larvae (L3), which may become accumulated in considerable numbers. 3 Infection of the final

hosts always occurs via the oral route. This can be directly by ingestion of eggs containing a third-stage larva (*S. trachea*) or by uptake of free third-stage larvae (*S. dentatus*) with contaminated food or indirectly by ingestion of intermediate hosts containing infectious third-stage larvae (possible in all three species). *BC* buccal cavity, *E* esophagus, *IN* intestine, *SH* sheath (cuticle of first- or second-stage larva), *UT* uterus

***Syngamus* Species,**

Fig. 2 Macrophoto of the opened trachea of a bird showing several of the blackish-appearing *Syngamus trachea* worms besides masses of coagulated blood

Prophylaxis

In stables, regular removal of feces.

Krone O et al (2007) Specific status and pathogenicity of syngamid nematodes in bird species. J Helminthol 81:67–73

Incubation Period

Three to five days.

Prepatent Period

Sixteen to twenty one days.

Patency

Several months (2–4).

Therapy

Benzimidazoles (e.g. flubendazole) had been proven to be highly efficacious as are macrocyclic lactones.

Further Readings

Holand H et al (2013) Temporal and spatial variation in prevalence of the parasite *Syngamus trachea*. Parasitology 140:1275–1286

Syngamus trachea

Name

Greek: *syn* = together, *gamein* = copulating (since the worms are mostly found in constant copula).

Classification

Species of the nematode family Syngamidae; worms live in the trachea (Fig. 1, page 1346).

Life Cycle

The adult worms (female 5–20 mm, male 2–8 mm) are found attached by their large buccal capsules at the wall of the trachea. They suck blood and thus appear reddish. The eggs are excreted with the host's faeces. The larva 3 develops within 2–4 weeks (often still within the eggshell). Paratenic hosts are earthworms. When orally taken up the L₃ wanders from the

***Syngamus trachea*, Fig. 1** Adults in the trachea of a bird

intestine via lung into the trachea, where the mature adults finally copulate. ► [Nematodes](#).

Prepatency

3 weeks, lifespan 3–7 months.

Therapy

Nematocidal Drugs.

Syngamy

Sexual process in which differently determined Gametes fuse completely, whether they include large (iso- or ► [anisogametes](#)) or only small (► [Microgametes](#)) amounts of cytoplasmic material. Syngamy always starts with the fusion of the

***Syphacia*, Fig. 1** LM of eggs of *Syphacia obvelata*

limiting membranes (Gametes, Figs. 4, 5), thus leading to a unicellular diplokaryon. Although karyogamy may be more or less delayed, depending on the species, no further fertilization can occur along the surface of such ► [zygote](#), whether a fertilization membrane (as in some eimerian species) is formed or not.

Syphacia

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of the nematode family Oxyuridae. *Syphacia* spp. (*S. muris*, *S. obvelata*) and *Aspiculuris* spp. occur in the ceca and colon of rats, mice, and hamsters. Males are 1.5 μm, females up to 4.5 mm long. The eggs of *S. obvelata* are crescent shaped (150 × 50 μm) and contain only a morula (*S. muris* contains a larva), Fig. 1.

Prepatent Period

Nine days.

Therapy

Nematocidal Drugs.

Syphilis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Syphilis, Fig. 1 Old painting of silver-stained *Treponema pallidum* bacteria

Name

The syphilis is named after the mythical shepherd *Syphilos* who was punished by the Olympic gods for blasphemy with a novel disease. The other name *lues* actually simply means epidemic, but it has been established to mean syphilis in particular.

Describers

The German microbiologists Schaudinn and Hoffmann described the wound pathogens (Group: spirochaetes) in the blood of patients in the secondary stage of the disease in 1905. Dr. von Wassermann – also a co-worker of Robert Koch – found a method for a serologic diagnosis in 1906.

History

One theory explains that syphilis was allegedly endemic in the New World and introduced to Europe by Spanish naval discoverers (leading to syphilis epidemics in Europe 1495, in India 1498, in China 1505). The other theory postulates that the syphilis already came from Central Africa to Europe in old Greek times. Today the disease is worldwide spread among humans.

Transmission

Genital contact, blood contact, and congenital transmission; about 12 million new infections every year.

Incubation Period

10–30 days.

Pathogen

The spirally coiled bacterium *Treponema pallidum* (old name *Spirochaeta pallida*; Fig. 1).

Symptoms of Disease

Primary stage: 3 weeks after the infection a so-called primary effect occurs at the place of the infection, genital or extragenital. It is a hard

ulcer (ulcus durum) which grows and soon after an ulcerous decomposition follows. **Secondary stage:** 8 weeks after the primary complex has disappeared. Affection of skin and mucosa, e.g., exanthema, loss of hair, general troubles. **Tertiary stage:** besides ulcers of the skin also gummata in the bones occur that often fall apart and cause a lot of damage. Neurosyphilis: affection of CNS, dementia.

Diagnosis

Serologic methods, clinic.

Treatment

Ehrlich and Hata discovered in 1906 the arsenic compound arsphenamine (Salvarsan[®]), which was intensively used until World War II. Since 1945, however, treatment is done by: penicillin, tetracycline, erythromycine, and cephalosporines.

Prophylaxis

Avoid unprotected sexual contact with strangers.

Notifiable Disease

In many countries yes, but registration of infected persons is often done anonymously.

Syringophilus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The mite *S. bipectinatus* (Fig. 1) lives inside the bases of feathers of birds and leads to their loss.

Systematics

Ute Mackenstedt
Institut für Parasitologie, Universität Hohenheim,
Stuttgart, Germany

General Information

For centuries, scientists have tried to detect, identify, describe, compare and analyze organisms and their amazing diversity. This endeavour is known as systematics, which can be defined as “the scientific study of the kinds and diversity of organisms and of any or all of the relationships among them.” Thus the final goal of systematic research is to detect and to identify species, to describe and to name them according to well-accepted rules and to place them into a hierarchical system which should consider the history of evolution, i.e., the phylogenetic relationships of species. Hillis and Moritz preferred to use systematics in the broad sense of the term, that is to elucidate both interspecific as well as intraspecific diversity, to study the variation within populations and the factors which causes population diversity, leading

finally to the development of new species. Therefore systematic research is concerned with ► [population genetics](#), ► [phylogeny](#), ► [speciation](#) and cospeciation (host-parasite interaction), taxonomy and nomenclature (► [Classification](#)).

Up to the 1960s of this century, organisms have been primarily identified and named on the basis of their morphology, biochemistry, ecology, epidemiology and behaviour, i.e., phenotypic markers. Phylogenies have been constructed using morphological, biochemical and behavioural characteristics. The classification of parasites is no exception. Individual parasites have been detected and identified on the basis of their morphology, the host-parasite interaction (i.e., host-specificity, number of hosts within the life cycle, pathogenetic effects on the host), their epidemiology, their behaviour and their geographical distribution. But many parasites have developed complicated Life cycles, including more than one host, and this is compounded by striking morphological differences at different stages in their development. Other parasites have evolved along long lines revealing striking morphological similarities although they are not closely related species. Parasitic ► [protozoa](#) or ► [nematodes](#) have little to offer in terms of morphological characteristics although the invention of the electron microscope provided new insights into the morphology of these organisms. Some of the parasites are very host-specific whereas closely related species are capable of infecting a variety of different hosts. Therefore the use of phenotypic characteristics for taxonomic purposes can be troublesome and of limited use as far as parasites are concerned, because the adoption of a parasitic lifestyle is often accompanied by dramatic alterations which make it difficult to identify these organisms, to distinguish between species, and it might finally blur the taxonomic position. However, the unambiguous identification and characterization of parasites is not only relevant for taxonomic purposes but also of special importance for diagnosis, treatment and disease control. A knowledge of phylogenetic relationships between parasites is fundamental for understanding parasitism in general and the results of these analyses may inspire new approaches in

diagnosis, vaccine development and treatment of important parasites in humans and animals. Detailed data on population diversity are relevant for the identification of cryptic species and may explain differences in virulence or drug resistance.

Phylogenetic Systematics

Only the very early attempts to compare and to describe organisms were independent from evolutionary aspects, but, as Mayr pointed out, since Darwin and Haeckel, the classification of species considers phylogenetic relationships as well. The last 30 years are characterized by numerous attempts to construct phylogenetic trees (► [Phylogeny/Phylogenetic Trees](#)) on the bases of reliable and repeatable methods. The most widely accepted method derived from the cladistic approach invented by Hennig (► [Phylogeny](#)). The increasing interest in cladistics (used in the broad sense of the term) gave rise to more sophisticated analytical methods, and the process of evaluating and analyzing the data resulted in different and sometimes conflicting classifications. This is especially true for unicellular eukaryotes (12, 13, 18, 19, 20, 53, 55, 63, 64, 113), which reveal an amazing diversity, exceeding by far that of multicellular eukaryotes. Andrews and Chilton criticized the fact that the term systematics is used nowadays in a very restricted manner, i.e., that many authors equate systematics with phylogenetics. It may be, that phylogenetic studies seem to dominate the research in systematics. However, Vickerman pointed out that, for example, the hitherto utilitarian systematics of unicellular eukaryotes may be replaced in the near future by a more natural system based on evolutionary relationships, resulting from the impact of new phylogenetics based on genetic information. Additionally, the careful interpretation of phylogenetic analyses provides valuable information on ► [population genetics](#) and their parameters.

Molecular Systematics

The molecular approach in systematics utilizes the genetic information of organisms which is stored

in genomes (including that of organelles) at the level of ► [chromosomes](#), gene sequences, and their secondary products, proteins. Molecular data offer some advantages, which can be successfully used for different purposes. Gene sequences (e.g., ribosomal RNA genes) are comparable although the species to be compared are disparate (e.g., helminths, humans, and bacteria). The rationale is that some homologous genes are present in all major lineages of organisms. Consequently molecular data can be used across a wide taxonomic range. Genes or parts of the genomes evolve at different rates, therefore molecular data may either elucidate microevolutionary events within populations, including the process of ► [speciation](#), or reveal the evolution of major lineages of species in the course of millions of years. Finally some genes evolve at constant rates allowing us to estimate the time of divergence using molecular clocks. The last 20 or 30 years have seen the invention of new molecular methods and vast improvements of sophisticated frameworks for analyzing the data. Additionally, Hillis and Moritz pointed out that systematic research, especially phylogenetics (► [Phylogeny](#)), and research in ► [population genetics](#) are now linked. Cooperation between these two disciplines is essential for understanding evolution.

The value of genetic information for systematic research is generally accepted and different methods, combined with mathematical frameworks, have been developed to analyze popula-

tion genetics, phylogeny, cospeciation, and to identify and characterize organisms. Page and Holmes complained about the tendency, with the invention of new methods, to consider the well-established and valuable ones as old-fashioned and unsuitable; this is clearly not acceptable. The combination of different approaches, using different methods and different characteristics, is necessary to address all aspects of systematic research. The final goal must be to use every possible source of information which is available to understand the diversity and evolution of organisms.

Syzygy

The term describes still motile stages consisting of 2 gamonts of ► [gregarines](#) or adeleideans (► *[Karyolysus lacertae](#)*) that are attached to each other; later (ensheathed or not) they start formation of gametes. The whole process is also called gamontogamy.

Szidat's Hypothesis

The more evolutionarily specialized the host group, the more specialized are the parasites. Thus the degree of specialization of the parasites may serve as a clue to the phylogenetic position of the host.

T

T Cell Exhaustion

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This term describes the severe decrease of T-cells in cases, when vertebrates including humans are infected by several viruses or by some protozoan parasites (e.g., *Leishmania* species, *Plasmodium* species, and *Toxoplasma gondii*).

stage of tabanids belong-
ing to the Brachycera. *AB*
abdomen, *AT* antennae, *AU*
eye, *HA* haltere

Tabanids, Fig. 3 Macrophoto of a specimen of the genus *Chrysops*, which transmits *Loa loa* worms in Africa

Tabanus, Fig. 1 Scanning electron micrograph of the head of a large specimen of the genus *Tabanus*. Note the extremely large compound eye, the saw-like mouthparts, and the horn-like left antenna. Tabanids search their prey by help of their compound eyes, which recognize movements of potential prey over far distances

horses, donkeys, and occasionally at humans. Their saliva contains tabanin, which avoids coagulation of blood. Their length ranges between 19 and 25 mm. Thus these blood suckers may harm considerably their hosts and are able to transmit mechanically various agents of diseases (e.g., blue tongue viruses). Related species are

T. bovinus (with green eyes) and *T. bromius* (greenish eyes, length 11–19 mm), occurring in Europe, North Africa, and Middle Asia.

Tâche Bleue

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

French name (also used as *tâche noir*) describing a skin reaction of humans due to infections with the tick-transmitted agent *Rickettsia conorii* at the biting sites (*Rickettsia*).

Tachinidae

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The family of blackish flies, the larvae of which parasitize in larvae of insects (maggots, caterpillars), while the adults visit mostly flowers. They are worldwide distributed. The largest European species is *Tachina grossa*, reaching a length of up to 18 mm.

Tachycardia

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *tachys* = quick; *cardia* = heart.

This term describes a symptom of high-speed heart pumping as a result, e.g., of infections by malaria parasites.

macrophages. The tachyzoites (syn. endozoites) are crescent shaped and reach a size of about $7 \times 2 \mu\text{m}$ (Figs. 1, 2, and 3).

Tachyzoite–Bradyzoite Interconversion

The 2 developmental (asexual stages) of *Toxoplasma* inside intermediate hosts change their activity if several conditions are given:

1. Tachyzoite ► **bradyzoite**
 - high pH
 - low pH
 - heat shock
 - mitochondrial inhibition
 - presence of nitric oxids
2. Bradyzoite ► **tachyzoite**
 - lack of nitric oxids
 - lack of IFN γ
 - lack of TNF α
 - lack of T cells
 - lack of IL-12

Tachyzoites, Fig. 1 Light micrograph of a macrophage parasitized by tachyzoites of *T. gondii*

Tachyzoites

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The name comes from Greek *tachys* = quick and *zoon* = animal and describes the quickly dividing (by ► **endodyogeny**) stages of ► *Toxoplasma gondii* inside ► **parasitophorous vacuoles** e.g., of

Tachyzoites, Fig. 2 Electron micrograph of a tissue cyst of *T. gondii* filled with bradyzoites

Tachyzoites, Fig. 3 Anterior end of a specially treated tachyzoite of *T. gondii* showing the conoid and the subpellicular microtubules

Taenia

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *tainia* = belt, band.

Classification

Genus of ► [Eucestoda](#).

Important Species

See Table 1.

Taenia, Table 1 Important species of the genus *Taenia*

Species	Length of adult worm (m)	Egg size (µm)	Final host	Prepatent period	Intermediate host (i.h.)/habitat	Stage inside intermediate host (i.h.)
<i>Taenia solium</i>	2–7	35–40	Humans	5–12	Pigs, humans/ many tissues	Cysticercus; <i>C. cellulosae</i>
<i>T. saginata</i>	6–15	35–40	Humans	10–12	Cattle/many organs	Cysticercus; <i>C. bovis</i> (<i>C. intermis</i>)
<i>T. asiatica</i>	5–7	35–40	Humans	8–18	Pigs, cattle, goat	Cysticercus
<i>T. (= Hydatigera) taeniaeformis</i>	0.6	35	Cats	7	Rats, mice/various organs	Strobilocercus; <i>Cysticercus fasciolaris</i>
<i>T. hydatigena</i>	1	20	Dogs	11–12	Ruminants/ ommentum	Cysticercus; <i>C. tenuicollis</i>
<i>T. ovis</i>	1	30	Dogs, foxes	6–7	Sheep/muscles	Cysticercus; <i>C. ovis</i>
<i>T. pisiformis</i>	0.5–2	35	Dogs, cats	6	Rodents/ ommentum	Cysticercus; <i>C. pisiformis</i>

Taenia, Fig. 1 Life cycles of ► *Taenia solium* (1–5) and *T. saginata* (1.1–5.1). (1–2.1) Adult worms live exclusively in the intestine of man and reach a length of 4–6 m (*T. solium*) or 6–10 m (*T. saginata*) often with about 2,000 proglottids. The ► scolex of *T. solium* is endowed with an armed rostellum (1). The terminal proglottids (10–20 × 5–7 mm) are characterized by a typically branched uterus filled with up to 100,000 eggs. On each day 6–7 of these proglottids detach and may either pass out with the feces or actively migrate out of the anus. (3, 3.1) As an excreted proglottid begins to dry up, a rupture occurs along the midventral and terminal regions and allows eggs to escape. The spherical eggs (40–45 µm; indistinguishable between species) originally have a hyaline outer membrane (Eggshell) which is usually lost by the time the eggs are voided with the feces. Thus, the eggs are bordered by a thick, striated ► embryophore surrounding the oncosphere (ON). (4, 4.1) When eaten by the intermediate host, the

oncosphere hatches in the duodenum, penetrates the mucosa, enters a venule, and is carried throughout the body. A bladder worm (► *Cysticercus*) of about 7–9 × 5 mm is formed, reaching infectivity in about 2 months (*C. cellulosae* in *T. solium*; *C. bovis*, *C. inermis* in *T. saginata*). When humans ingest eggs of *T. solium* or a terminal proglottid is destroyed inside the intestine, cysticerci may also readily develop in many organs including brain and eyes. These infections lead to severe dysfunctions depending on the parasitized organ (► *Cysticercosis*). (5) A person becomes infected when a bladder worm is eaten along with raw or insufficiently cooked meat. The evaginating ► scolex becomes attached to the mucosa of the small intestine and matures in about 5–10 weeks. infections of humans are apparently successful, if cysticerci within the meat of pigs and cattle (!) were ingested. The adult worms reach in humans a length of 4–8 m; the cysticerci are found in the liver of pigs and rarely cattle.

4. **Symptoms of disease:** Similar to those after infections with ► *T. solium*.
5. **Diagnosis:** Infected persons excrete typical *Taenia* proglottids. Since eggs are typical for all *Taenia* species, species differentiation can only be made by PCR.
6. **Infection:** Oral uptake of cysticerci with raw or undercooked meat (liver) of pigs and (rarely) cattle.
7. **Prophylaxis:** Avoid eating raw meat in endemic regions.
8. **Incubation period:** 8–10 weeks.
9. **Prepatent period:** About 4 weeks.
10. **Patency:** Years (recent discovery of this worm does not yet allow definitive conclusions).
11. **Therapy:** Praziquantel is the drug of choice (1×10 mg/kg bodyweight).

Taenia asiatica

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

1. **Name:** Greek: *tainia* = tape. Latin: *asiaticus* = belonging to/coming from Asia.
2. **Geographic distribution/epidemiology:** East Asia.
3. **Morphology/life cycle:** This species looks morphologically similar to ► *T. solium* except for the fact that the scolex possesses only remnants of hooks. Its life cycle runs similarly to that of ► *T. solium*, while molecular biological investigation showed close relations to ► *Taenia saginata*. Main intermediate hosts are pigs; however, cysticerci had also been found in muscles of goats, bears, monkeys, dogs, and even in cattle. However,

Taenia asiatica Peculiarities

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This tapeworm species has a lifecycle like *T. solium* involving humans as final and pigs/wild boars as intermediate hosts, where the very tiny (~2 mm) cysticercus is found in the liver. The gravid (= terminal) proglottids are very similar to those of ► *Taenia saginata*, while eggs are similar to both human *Taenia* species. The geographic distribution of this tapeworm comprises exclusively Asian countries such as China, Indonesia, Japan, Korea, Laos, Malaysia, Nepal, the Philippines, Thailand, and Vietnam.

The pathogenicity for humans of the adult worms appears low; symptoms are mostly unspecific and become only rarely severe. The dramatic occurrence of cysticerci in the brain of humans (as it occurs in *T. solium*) has not yet been proven. However, numbers of diseased people are high, and economic losses due to infected pigs are very important.

Taenia saginata

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *tainia* = band, tape. Latin: *saginatus* = strong, thick. English: beef tapeworm of humans.

Geographic Distribution/Epidemiology

Worldwide: WHO estimates that nearly one million of humans are infected, especially in countries with intensified cattle farming.

Morphology/Life Cycle

The life cycle of this tapeworm is diagrammatically depicted in Fig. 1 of the keyword ► *Taenia solium*, since many features of both human tapeworms are very similar. *T. solium* reaches a length of 6–10 m. Its scolex (measuring 1–2 mm) is also armed with four strong suckers, but rostrum with hooks is lacking (Fig. 1). The terminal proglottids, which are excreted singly or in groups of 2–3, measure up to 2 cm × 7 mm and thus are considerably larger than those of *T. solium*; also their uterus has much more lateral branches (up to 35–40) than that in the terminal proglottids of *T. solium* (Fig. 2). The spherical eggs are morphologically indistinguishable from those of *T. solium* and measure also 30–40 µm in diameter (Fig. 3).

Taenia saginata, Fig. 1 Light micrograph of the unarmed scolex of *T. saginata*

Taenia saginata,**Fig. 2** Light micrograph of a proglottid of *T. saginata***Taenia saginata, Fig. 3** Light micrograph of an egg of *T. saginata*

If cattle ingest such eggs, the typical cysticercus stages are formed in muscles; however, they reach mostly only diameters of 7–9 mm and are thus smaller than those of *T. solium* in pigs.

Symptoms of Disease

The symptoms in humans are very similar to those of ► *T. solium* with respect to their intestinal location. However, in contrast to *T. solium*, *T. saginata* does not form cysticerci in humans, if they ingest occasionally eggs of this tapeworm. Thus there are no symptoms of cysticercosis due to *T. saginata*.

Diagnosis

The diagnosis of a taeniasis is based on observations of typical large proglottids in/on the stool and on microscopic determination of the typical eggs by help of concentration methods (S.A.F.C., ► [M.I.F.C.](#), ► [flotation](#)).

Infection

Oral uptake of cysticerci in raw or undercooked meat of infected cattle. This may occur repeatedly, since immunity is not reached.

Prophylaxis

Avoid to eat raw or undercooked meat. However, deep-freezing of meat for 3–4 days at -18°C to 24°C will kill enclosed cysticerci.

Incubation Period

Eight to twelve weeks (however, symptoms may be completely absent).

Prepatent Period

Eight to twelve weeks.

Patency

Years or even more.

Therapy

Praziquantel is the drug of choice ($1 \times 10\text{--}50$ mg/kg bodyweight).

Geographic Distribution/Epidemiology

Worldwide.

Morphology/Life Cycle

The adult hermaphroditic tapeworm reaches a length of 3–6 m and lives in contrast to its English trivial name inside the intestine of humans and primates (Figs. 1, 2, 3, and 4). The scolex is armed by a hooked rostrum and four suckers, which help this tiny, only 1–2-mm-sized adhesion apparatus which remains firmly attached at the wall of the small intestine. There are in total 26–32 hooks, which comprise small and large ones (Fig. 2). The body = strobila of the adult worm represents a long whitish band which is segmented and thus appears as a “chain” of so-called proglottids. Close to the scolex and the following neck (= zone of differentiation) the proglottids contain fully active male sexual organs (numerous small spherical testes). In the middle region of the worm, the proglottids are filled with the organs of the female system, and in the terminal portion, the proglottids contain the branched uterus, which is filled with up to 80,000 embryonated eggs (Figs. 3 and 4). The 4–8 last proglottids are daily disrupted and can be found (often slightly moving) in/on the human stool. The whole life cycle is diagrammatically depicted in Fig. 1.

Symptoms of Disease (Taeniasis, Cysticercosis)

Although adult tapeworms reach a considerable length, symptoms of disease are rare and mostly rather mild. Most common symptoms are abdominal pain, loss of weight, disturbances in digestion, anal itching, and hungry feeling besides phases of obstipation. The blood screening shows a mild eosinophilia. In general, mostly only one adult tapeworm is present. Apparently, one suppresses the development of others, which was described by Küchenmeister, who in the eighteenth century infected volunteers (prisoners) with several cysticerci.

Taenia solium

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *tainia* = tape. Latin: *solus* = alone.
English: pork tapeworm.

T

Taenia solium, Fig. 1 Life cycle of *T. solium* (1–5) and *T. saginata* (1.1–1.5) 1–2.1 Adult worms live exclusively in the intestine of man and reach a length of 4–6 m (*T. solium*) or 6–10 m (*T. saginata*) often with about

Taenia solium, Fig. 2 Light micrograph of the scolex of *Taenia solium*

Taenia solium, Fig. 3 Macrophoto of a terminal proglottid

Taenia solium, Fig. 1 (continued) 2,000 proglottids. The **scolex** of *T. solium* is endowed with an armed rostellum (*1*). The terminal proglottids ($10\text{--}20 \times 5\text{--}7$ mm) are characterized by a typically branched uterus filled with up to 100,000 eggs. On each day, 6–7 of these proglottids detach and may either pass out with the feces or actively migrate out of the anus. 3, 3.1 As an excreted proglottid begins to dry up, a rupture occurs along the midventral and terminal regions and allows eggs to escape. The spherical eggs ($40\text{--}45$ μm ; indistinguishable between species) originally have a hyaline outer membrane (eggshell) which is usually lost by the time the eggs are voided with the feces. Thus, the eggs are bordered by a thick, striated **embryophore** surrounding the oncosphere (ON). 4, 4.1 When eaten by the **intermediate host**, the oncosphere hatches in the duodenum, penetrates the mucosa, enters a venule, and is carried throughout the body. A bladder worm

(► **cysticercus**) of about $7\text{--}9 \times 5$ mm is formed, reaching infectivity in about 2 months (*C. cellulosae* in *T. solium*; *C. bovis*, *C. inermis* in *T. saginata*). When humans ingest eggs of *T. solium* or a terminal proglottid is destroyed inside the intestine, cysticerci may also readily develop in many organs including brain and eyes. These infections lead to severe dysfunctions depending on the parasitized organ (► **cysticercosis**). 5 A person becomes infected when a bladder worm is eaten along with raw or insufficient cooked meat. The evaginating ► **scolex** becomes attached to the mucosa of the small intestine and matures in about 5–10 weeks. BL bladder of cysticercus; EB ► **embryophore**; EX excretory vessels; GP genital pore; HO hooks of oncosphere; ON Oncosphere; RH rostellar ► **hooks**; SC scolex; SU ► **sucker**; UE uterus filled with eggs

Taenia solium, Fig. 4 Light micrograph of stained terminal proglottids of *T. solium*

Taenia solium, Fig. 5 Macrophoto of pork meat containing several whitish-appearing cysticerci of *T. solium*

On the other side, porcine ► [cysticercosis](#) in humans may end fatal, if humans are infected by oral uptake of worm eggs from own or foreign feces and cysticerci are formed in their brain (Fig. 7). There, the cysticerci may reach the same dimensions (~2 cm) as in the intermediate host pig (Figs. 5 and 6), and thus they introduce more or less severe damages and functional disturbances depending on their location in the brain.

Taenia solium, Fig. 6 Macrophoto of a cysticercus which consists of a translucent bladder containing the scolex and anlage of the adult tapeworm

Taenia solium, Fig. 7 Human head with several *T. solium* cysticerci (arrows) (From Prof. Dr. Eichenlaub in Mehlhorn (2012))

Taenia solium, Fig. 8 Cysticercus with protruded scolex in a human eye

The disease is then called ► [neurocysticercosis](#). In rare cases, such cysticerci may also occur in the eyes (Fig. 8).

Diagnosis

In general, 6–10 whitish proglottids appear in intervals in the stool of infected humans and can be seen by the naked eye, since they reach a length of 8–12 mm (Fig. 3). In fresh feces, they may even be recognized by typical constriction movements. A differentiation between *T. solium* and *T. saginata* can be done by microscopic investigation of fixed and stained terminal proglottids. While the uterus in the proglottids of *T. solium* has about 10–13 lateral branches at both sides (Fig. 4), those of *T. saginata* mostly contain 20–35 branches. **Attention:** It is very important to fix the proglottids before the above-described inspection; otherwise infection risks for a ► [cysticercosis](#) exist.

Typical eggs of *Taenia* worms can also be found in feces, if the proglottids have been squeezed (Figs. 1, 9 and 10). The eggs can be demonstrated light microscopically when using concentration methods such as ► [flotation](#), SAFC, and ► [MIFC](#). The eggs are spherical,

measure 30–40 µm in diameter, and possess an outer thin layer, which is often disrupted, so that only the inner thick, striated layer (embryophore) is retained (Fig. 9). Inside the embryophore, the six-hooked larva = oncosphere is enclosed, which infects pigs and humans.

Infection

The ingestion of cysticerci in raw meat of infected pigs (Figs. 5 and 6) leads to the development of an adult tapeworm inside the intestine, while ingestion of eggs by contact with contaminated feces may end in a cysticercosis in any of the human organs.

Prophylaxis

Avoidance of ingestion of raw or undercooked meat of pigs. Cysticerci, however, lose infectiosity, if the meat is deep frozen at –18 °C for at least 24–48 h. Avoid contact with human feces (e.g., on wild camping places or at resting places along highways).

***Taenia solium*,**

Taenia solium,

Fig. 10 Light micrograph of an egg of *Taenia solium* and other tapeworms

Incubation Period

It takes about 8 weeks until first symptoms occur due to growing adult worms. In cases with infections due to ingested worm eggs (Fig. 9), first symptoms of a cysticercosis occur depending on infected organs about 4–12 weeks after infection.

Prepatent Period

Eight to eighteen weeks after infection, first proglottids occur in the feces.

Patency

Adult worms can persist in humans for 20–30 years. Cysticerci survive mainly for 1–2 years (however, immunity does not occur).

Therapy

Drug of choice to treat adult taeniasis is praziquantel (1×10 mg/kg bodyweight). Niclosamide (1×2 g) and mebendazole (2×200 mg daily for 3 days) are also effective. Treatment should be accompanied by ingesting laxanthia plus ricinus oil in order to expel quickly

the dead worm and thus to avoid self-infection due to digestion of proglottids inside own intestine and penetration of oncosphere into the intestinal wall.

Taenia Species of Dogs and Cats

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Taenia Species of Dogs and Cats, Fig. 1 Scanning micrograph of the scolex of *T. pisiformis*

1. **Name:** Greek: *tainia* = tape, band; *hydatis* = bladder containing water. Latin: *pisum* = pea; *forma* = shape; *multiceps* = with many heads; *crassiceps* = with fat ends; *ovis* = sheep.
2. **Geographic distribution/epidemiology:** Worldwide with a broad spectrum of hosts.
3. **Morphology/life cycle:** There are several rather common species:
 - 3.1 ***Taenia pisiformis*** (Figs. 1, 2, 3, 4, and 5). Adult worms reach a length of up to 2 m. The gravid terminal proglottids measure about 8–10 × 4.5 mm and their uterus is composed of a median strand and 8–14 pairs of lateral ones (Fig. 2). **Intermediate hosts** are rabbits, hares, and several rodents which harbor the pea-sized, whitish spherical cysticercus larva.
 - 3.2 ***Taenia ovis*** (Figs. 5 and 6). The adult tapeworm reaches a length of 1.2–1.5 m. **Intermediate hosts** are sheep.

Taenia Species of Dogs and Cats, Fig. 2 Light micrograph of ruthenium red-stained terminal proglottids of *T. pisiformis*. Note the pairs of the laterally branched uterus

Taenia Species of Dogs and Cats, Fig. 3 Light micrograph of a typical *Taenia* egg, which is bordered by the thick embryophore wall, while the tiny outer layer is already lost. Inside the oncosphaera larva can be seen

Taenia Species of Dogs and Cats, Fig. 4 Macrophoto of the omentum region of a rodent which is filled by numerous cysticerci (arrows) of *T. pisiformis*

- 3.3 *Taenia hydatigena* (Fig. 5). This species reaches a length of 1 m; its terminal proglottids measure 12×6 mm. **Intermediate hosts** are different plant feeders.
- 3.4 *Taenia* (syn. *Hydatigena*) *taeniaeformis* (Fig. 7). This tapeworm mainly occurs in the intestine of cats. The uterus of the terminal proglottids shows 5–9 sack-like protrusions. Intermediate hosts are rats, mice, and many other rodents, which contain already the so-called strobilocercus (Fig. 6), which represents already the anterior portion of the later adult worm, since it reaches lengths of up to 30 cm.
- 3.5 *Taenia krabbei* (syn. *T. cervi*). This tapeworm reaches a length of up to 2.5 m. The terminal proglottids measure $12\text{--}15 \times 5\text{--}7$ mm and include a uterus with 10–12 lateral branches. **Intermediate hosts** are deer and stags, the muscles of which contain the cysticercus, which look similar to those of *T. ovis* (Fig. 6).
- 3.6 (Fig. 5). This tapeworm reaches a length of 1 m; its terminal proglottids measure $8 \times 12 \times 5$ mm and show 14–26 pairs of branches of the uterus. **Intermediate hosts** are mainly sheep. The larva is described as *Coenurus cerebralis* (Fig. 8), also in the brain of humans and many other omnivores.
- 3.7 *Taenia serialis* reaches a length of up to 70 cm. The uterus of terminal proglottids, which measures $8\text{--}16 \times 3\text{--}5$ mm, shows 20–26 pairs of branches (Fig. 5). **Intermediate hosts** are many species of rodents. Also humans may become infected.
- 3.8 *Taenia crassiceps* reaches a length of about 50 cm and is after *Dipylidium caninum*, the second most common tapeworm of dogs. **Intermediate hosts** are mice, which harbor the cysticercus larva. This stage is able to reproduce inside mice by asexual division.

Taenia Species of Dogs and Cats, Fig. 5 Diagrammatic representation of terminal proglottids of tapeworms of dogs and cats showing the typically branched uteri

Taenia Species of Dogs and Cats, Fig. 6 Macrophoto of cysticerci of *T. ovis* in the muscles of a sheep

Taenia Species of Dogs and Cats, Fig. 7 Light micrograph of the strobilocercus larva of *Taenia taeniaeformis* (SN = one of the four suckers)

Taenia Species of Dogs and Cats,

Fig. 8 Micrograph of the coenurus larvae of *Taenia multiceps* with translucent anlagen of several protoscolices

- 4. **Symptoms of disease:** In dogs and cats, there occur very often no or only slight respectively unspecific symptoms such as loss of weight, stress, and digestion problems.
- 5. **Diagnosis:** The genus determination may be done by microscopical analysis of the eggs (Fig. 3), while for species determination structures of terminal proglottids are useful (Fig. 5). Of course exact diagnosis needs molecular biological methods such as PCR, etc. However, since cure of the final host (cats, dogs) as well as of humans (accidental intermediate hosts) is based on praziquantel in any way, exact species determination is not needed.
- 6. **Infection:** Dogs and cats are infected by ingestion of larval stages in the tissues of intermediate hosts, while humans become infected by oral uptake of eggs in the feces of final hosts.
- 7. **Prophylaxis:** Cats and dogs should not be fed with raw meat. Humans should avoid contact with feces of dogs and cats.
- 8. **Incubation period:** Species depending: several weeks.
- 9. **Prepatent period:**

<i>Taenia pisiformis</i>	~ 50 days
<i>Taenia ovis</i>	~ 60–130 days
<i>Taenia hydatigena</i>	~ 50–70 days
<i>Taenia taeniformis</i>	~ 36–80 days
<i>Taenia</i> (syn. <i>Multiceps</i>) <i>multiceps</i>	~ 45–57 days
<i>Taenia crassiceps</i>	~ 31–42 days

- 10. **Patency:** Years (often 2–5).
- 11. **Therapy:** Most used drug of choice is praziquantel (1 × 5 mg/kg bodyweight) orally or subcutaneously.

Taeniasis with *T. saginata* and *T. solium* ► [tape-worms](#) (► [Taenia](#)) in the small intestinal lumen is largely asymptomatic. Microscopic lesions have not been described, except for slight ► [eosinophilia](#). However, after ingestion of *T. solium* eggs humans can act as intermediate hosts. The larval cysts develop in almost any tissue and can cause serious damage especially when they involve special areas of the brain (► [Cysticercosis](#)).

Main Clinical Symptoms

Loss of weight, ► [abdominal pain](#), ► [anal pruritus](#).

Incubation Period

Eight weeks.

Prepatent Period

Eight to eighteen weeks.

Patent Period

Twenty-five years in man.

Diagnosis

Occurrence of typical white proglottids in feces (Fig. 1).

Taeniasis, Man, Fig. 1 Typical singly excreted proglottis of *Taenia* worms

Prophylaxis

Avoid eating raw meat.

Therapy

Treatment with praziquantel, see ► [Cestodocidal Drugs](#).

Tapeworms of Birds

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Davaine (1812–1882), Railliet (1828–1902): French parasitologists. Greek: *proglottis* = tip of tongue; *tainia* = tape; *amoibe* = changing shape; *choanos* = funnel. Latin: *fimbria* = fringe.

Geographic Distribution/Epidemiology

Worldwide spread, but most not very pathogenic infections (Table 1).

Morphology/Life Cycles

1. *Davainea proglottina* is found relatively often in many species of chicken birds. The adult

worms occur in the anterior intestine and reach a length of only 4–5 mm comprising 4–9 proglottids with diameters of 0.3–0.6 mm. The scolex is armed with a protrudable rostellum consisting of two rings with 30–50 small hooks each. The glassy transparent adult worms are attached at the intestinal wall of their hosts by help of its suckers, which possess fine hooks. The pores of the genital system open at the anterior pole of each proglottid but alter regularly the side of the proglottids. The shape of the eggs (55 × 36 µm) is similar to that of *Hymenolepis* (Fig. 1) and is situated singly in capsules inside the parenchyma of the proglottids. Intermediate hosts are unshelled snails (e.g., *Arion*, *Limax*).

2. *Raillietina species*. The adult worms are found in many bird species, reach a length of 25 cm (e.g., *R. tetragona* in chicken), and have a width of about 4 mm. These worms produce many proglottids and are attached at the intestinal wall of their hosts by help of its armed rostellum consisting of two rings provided with 8–10 rows of tiny hooks. The pores of the sexual systems lay unilateral at one side of the worms, which are mainly found in the midgut region. Six to twelve eggs are enclosed in capsules and look like those of the species of *Hymenolepis*. Depending on the species, the following intermediate hosts are used: beetles, snails, domestic flies, or ants (the latter is on the case of *R. tetragona*).

3. *Amoebotaenia species*. These wedge-shape tapeworms are mainly found in farmed

Tapeworms of Birds, Table 1 Characteristics and size of proglottids and eggs of common tapeworms of chicken (After Rommel et al. 2000)

Species	Proglottids	Eggs
<i>Amoebotaenia cuneate</i>	Proglottids, broader than long, 0.5 × 1.5 mm	Eggs spherical, 47 × 42 µm, surface undulated
<i>Choanotaenia infundibulum</i>	Proglottids, 3–5 mm long × 0.5–1 mm wide	Ovoid eggs, 54 × 47 µm, surface with two lateral protrusions
<i>Davainea proglottina</i>	Proglottids are ovoid, 2 mm long and transparent	Eggs spherical, 50 × 45 µm
<i>Echinoleps carioca</i>	Proglottids are 2–7 mm long × 1 mm wide	Eggs ovoid, 76 × 62 µm, egg wall has several layers
<i>Raillietina cesticillus</i>	Proglottids, spherical, 3 mm thick, whitish!	Eggs spherical to ovoid, 93 × 74 µm

Tapeworms of Birds, Fig. 1 Diagrammatic representation of the life cycle of *Hymenolepis* species of humans and rodents and *Hymenolepis* (syn. *Echinolepis*) *carioca* of chicken. A. Final hosts. B. Intermediate hosts. 1, 2 Egg containing the typical oncosphaera larva. 3 Eggs are ingested by intermediate hosts feeding feces. 4, 5 During metamorphosis eggs also reach adult stages of intermediate

host, and after hatch the cysticercoid larva is produced. If this larval stage is ingested by final hosts (within total or partial intermediate hosts), the adult tapeworm is formed. EM embryophore, EX excretion channel, ES egg shell, GP genital porus, HK hooks of oncosphaera and cysticercoid, ON oncosphaera, OV ovary, SU sucker, TE testis, VD vas deferens, VG vagina, VI vitellarium

(house) birds and reach a length of only 4 mm with 12–14 proglottids, and their rostellum shows up to 14 hooks. The genital pore alternates irregularly at the sides of the proglottids. The eggs (also those of the *Hymenolepis* types) are enclosed inside a sack-like uterus. Intermediate hosts are earthworms.

4. **Choanotaenia species.** The adult worms reach a length of up to 25 cm and a width of only 3 mm. Their rostrum contains up to 20 hooks. Their genital pores alternate regularly. The eggs are of the *Hymenolepis* type, but possess filamentous protrusions. Intermediate hosts are dung beetles and *Musca* flies.
5. ***Hymenolepis* species.** There exist many species in farmed and in wild birds. Their importance is mostly low, except

for specimens of *Hymenolepis* (syn. *Drepanidotaenia*) *lanceolatum* in the intestine of goose and ducks, which reach a length of 15 cm. Since the posterior proglottids have width of up to 2 cm, this tapeworm appears lance-like. Intermediate hosts are crustaceans of the species of *Gammarus*, *Cyclops*, and *Diaptomus*. *Hymenolepis* (syn. *Echinolepis*) *carioca* reaches a length of 8 cm; *Echinolepis anatis* reaches even 30 cm. The testes are characteristic, since they appear always as three ball-like structures (Fig. 1). The rostellum of the tapeworms in chicken, ducks, and water birds is mostly unarmed; however, the four suckers may contain tiny hooks. Intermediate hosts are mainly dung beetles and *Musca* flies.

6. ***Fimbriaria* species.** The adults which occur in the intestine of chickens and water birds may reach a length of 40 cm and a width of 5 mm. Their terminal end shows a broad, leaflike pseudoscolex instead of a typical scolex with four suckers. The eggs are excreted unembryonated, contain an operculum, and measure about 45 µm in length. Thus, they appear like eggs of trematodes. Intermediate hosts are crustaceans like *Cyclops*, *Gammarus*, and *Diaptomus*.

Symptoms of Disease

In cases of heavy infections: diarrheas, reduced weight gain and reduced egg laying, eventually death.

Diagnosis

Demonstration of proglottids and eggs (Fig. 1) in the feces.

Infection

Oral uptake of intermediate hosts with enclosed larvae (cysticercoids).

Prophylaxis

Keep away possible intermediate hosts from bird farms; take away feces at short intervals.

Incubation Period

Variable, up to 2 weeks.

Prepatency

Two weeks (*D. proglottina*, *H. lanceolatum*, *E. carioca*) or 3 weeks (*Choanotaenia* species,

R. tetragona, *R. cesticillus*) or even 4 weeks (*A. cuneata*).

Patency

Mostly only a few weeks.

Therapy

Praziquantel (1 × 10 mg/kg bodyweight), niclosamide in food (2–6 days corresponding 20 mg/kg bodyweight), or mebendazole in food (7 days each 60 ppm).

Tapeworms of Cattle Sheep and Other Ruminants

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Moniez = French helminthologist (1852–1936).
 Greek: *thysanos* = fringe. Latin: *ovitellus* = without yolk; *expansus* = enlarged.
 Stiles = English parasitologist. Greek: *anaplon* = unarmed; *kephale* = head.

Geographic Distribution/Epidemiology

Worldwide, often prevalence rates of 10–30 %, in lambs often up to 50 %.

Tapeworms of Cattle Sheep and Other Ruminants,

Fig. 1 Macrophoto of portions of an opened sheep intestine filled with *Moniezia* worms

Morphology/Life Cycle

- (a) ***Moniezia* species** (e.g., *M. expansa*, *M. benedeni*) are found mostly in sheep (Figs. 1 and 2) and reach considerable length and width (*M. expansa*, 10 m × 2.5 cm; *M. benedeni*, 4 m × 1.6 cm). The proglottids have each two sets of sexual organs being situated at their lateral sides. The scolex is characterized by four lateral slit-like suckers with hooks at the anterior end. The eggs (~about 60 μm–90 μm) are polymorphous and contain already an oncosphaera larva when deponed. Intermediate hosts are so-called oribatid mites, which live on grass of meadows. This explains the high infection rates. Inside the oribatids (e.g., *Trichoribates* sp., *Scheloribates* sp., *Pilogalumna* sp.), the development of the cysticercoids takes up to 3 months.
- (b) ***Avitellina* species** (e.g., *A. centripunctata*; Fig. 2) are found in South Europe, Africa, and Asia in the small intestine of a large spectrum of ruminants. They reach a length of up to 3 m. The strobila seems to be non-segmented since the height of the terminal proglottids is only 3 mm. There is only one lateral pore of each sexual system and only a single so-called paruterine organ (Fig. 3; PA). The therein included eggs
- measure 45 × 20 μm. Intermediate hosts are oribatid dust mites (Psocoptera) and Collembola.
- (c) ***Thysanieza* and *Thysanosoma* species** (e.g., *T. actinoides* in North and South America) are found in the bile ducts and small intestines of their hosts. They reach a length of up to 2 m. Their proglottids have a width of up to 1 cm (Fig. 3). The sexual pores alternate at the side (one left, next right). The uterus forms several paruterine organs. The tiny eggs have diameters of 25 μm. Intermediate hosts are dust mites (Psocoptera).
- (d) ***Stilesia* species** (e.g., *S. globipunctata*, *S. hepatica*) live in the intestine and in the bile ducts of their hosts (Fig. 3). *S. globipunctata* is found in South Europe, Africa, and Asia, while *S. hepatica* occurs in tropical Africa and Asia. The adult worms reach a length of only 2–5 cm, and the proglottids contain always two paruterine organs (Fig. 2), which are closely filled by the 25 μm-sized spherical eggs. Intermediate hosts are oribatid mites.

Symptoms of Disease

Mostly, only young animals show severe symptoms of disease such as weakness, loss of weight,

**Tapeworms of Cattle
Sheep and Other
Ruminants,**

Fig. 2 Scanning electron micrographs of *Moniezia expansa*. (a) Portion of the strobila; (b) central proglottid; (c) scolex. GP genital porus, MO testis, OV ovary, PR proglottids, SN sucker, VI vitellarium

anemia, loss of hair, colics, diarrheas, obstipation, paralysis, and even death cases.

Diagnosis

Determination of the proglottids excreted in the feces.

Infection

Oral uptake of infected mites within food.

Prophylaxis

Practically not possible.

Incubation Period

Four to eight weeks.

Prepatent Period

Depending on the species: 3–4, 8, or 9 months.

Tapeworms of Cattle Sheep and Other Ruminants, Fig. 3 Diagrammatic representation of proglottids of different tapeworms of ruminants. *EL* longitudinal excretion channel, *EQ* crossing excretion channel, *HO* testis,

OB ovary region, *OV* ovary, *PA* paruterine organ with eggs, *PR* central proglottids, *TP* terminal proglottids, *UPA* uterus with anlage of the paruterine organ, *VI* vitellarium

Patency

Depending of the species up to 1 year.

Treatment

From the point of economy mostly young sheep should be treated. Effective cestocides are niclosamide (100 mg/kg bodyweight), praziquantel

(5 mg/kg bodyweight), albendazole (7.5 mg/kg bodyweight), fenbendazole (5–10 mg/kg bodyweight), mebendazole (15–20 mg/kg bodyweight), or oxfendazole (5 mg/kg bodyweight).

Tapeworms of Fish

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *karyon* = nucleus, nut; *phyllon* = leaf; *pseudo* = wrong; *protheus* = anterior; earlier; *kephalon* = head; *kyaneos* = blueish; *bothrium* = groove; *laticeps* = wide reaching.

Geographic Distribution/Epidemiology

Worldwide.

Morphology/Life Cycle

In the intestine of fish (salt or freshwater fish) the adults of many tapeworms of several species may occur, while larvae of the other species are found in the body cavity or in the muscles. There are many different groups of fish tapeworms. Some important ones are selected:

- (a) ***Caryophyllidae*** (e.g., *Caryophyllaeus laticeps*). These unsegmented parasites reach a length of 3 cm. The anterior end looks like a carnation plant. Inside only one set of sexual organs occurs. The male sexual organs consist of up to 400 small spherical testes. The eggs reach a size of $65 \times 37 \mu\text{m}$ and are excreted with the host's feces. Intermediate hosts are oligochaetes (Tubificidae, *Tubifex*). Final hosts are carps and related fish (Fig. 1).
- (b) ***Pseudophyllidea*** are characterized by two sucking apparatus (bothria at the scolex).
 - ***Triaenophorus* species** (Fig. 2) possess in addition to the two bothria four hooks at the scolex. This worm is considered to be

Tapeworms of Fish,
Fig. 1 Scanning electron micrograph of armed and unarmed scolices of several tapeworms of fish. (a) *Hepatoxylon* sp. (b, c) *Caryophyllidae*

Tapeworms of Fish, Fig. 2 Tapeworms of fish. (a, b) Anterior poles of the pseudophyllidean tapeworm *Triaenophorus lucii* from pikes. (c) Anterior pole of the larva of *Diphyllobothrium latum*. (d) *Ligula intestinalis*

plerocercoid in the body cavity of carps. (e) Plerocercoid of *Schistocephalus solidus* in the body cavity of sticklebacks. (f, g) Anterior pole and strobila of *Eubothrium* species

the most dangerous tapeworm for fish. *T. lucii* (syn. *T. nodulosus*) infects pikes, perches, and reaches a length of up to 15 cm by a width of up to 4 cm. *T. crassus* (in pikes) reaches a length of up to 40 cm. Both species use small crustaceans (*Cyclops* species) as first intermediate hosts and trouts as second one. In trouts the plerocercoids reach a length of up to 10 cm being situated in and around the liver. The operculated eggs measure $50 \times 30 \mu\text{m}$. The same fish may harbor at the same time plerocercoids as well as adults.

- ***Eubothrium* species** are widely distributed (Fig. 2). *E. crassum* parasitizes in salmonids, reaches a length of 80 cm and a width of up to 6 mm and is characterized by an unarmed scolex with two lateral sucking grooves. The eggs measure $55 \times 40 \mu\text{m}$ and contain the so-called coracidium larva

which bears cilia for movements in water. First intermediate hosts are *Cyclops* species; second ones are plant feeding fish but also the perch.

- ***Cyathocephalus* species** occur in many fish species, reach a length of 5 cm, and possess an unarmed pitcher-like scolex. The eggs measure $48 \times 30 \mu\text{m}$. Intermediate hosts are copepod crustaceans.
- ***Bothriocephalus* species** (e.g., *B. scorpii*, *B. cuspidatus*) reach in various salt and freshwater fish a length of up to 1 m with a width of 6 mm. The scolex shows a discus-like sucker. The sexual openings are situated in a median longitudinal groove. The operculated eggs measure $70 \times 30 \mu\text{m}$. First intermediate hosts are copepod crustaceans; second intermediate hosts are nonraptor fish, which contain the 2 cm long plerocercoid larvae.

- (c) **Tetraphyllidea:** The adult worms parasitize in marine raptor fish. Their scolex shows four leaf-like protrusions which often are provided with suckers. *Rhinebothrium* species reach in sharks a length of up to 7 cm. First intermediate hosts are copepod crustaceans, while plankton feeding fish act as second intermediate hosts. The eggs are spherical and measure 40–50 µm in diameter but possess in some species polar filaments.
- (d) **Proteocephalida:** The scolex of these species shows four suckers and an apical additional one. The worms are mostly rather tiny measuring only 1–10 mm (a few species, however, reach even a length of 20 cm up to 100 cm). The eggs are spherical and measure species-specifically 20–50 µm in diameter. Intermediate hosts are *Cyclops* crustaceans, within which the infectious plerocercoid is formed.

Symptoms of Disease

The symptoms are species dependent and very variable; common are reduced growth, loss of weight, obstipation of the intestine, lesions of the intestinal wall, increase of leucocytes, and often occurrence of anemia.

Diagnosis

Microscopic analysis of eggs or microscopic inspection of proglottids within feces.

Infection

Oral uptake of organisms bearing the plerocercoid larvae.

Prophylaxis

Impossible in free-living marine fish. In case of pond fish regular drying of the basins decreases the worm load significantly.

Incubation Period

Species-specific 2–10 weeks.

Prepatent Period

Two to ten weeks.

Patency

Several months, often lifelong.

Treatment

Impossible in free-living fish. In pond cultures, praziquantel or niclosamid as food addition. In case of salmonids fenbendazole (2 days 5–8 mg/kg in food) was successful. In case of aquaria fish the product Tremazol® (praziquantel) is the therapy of choice (Fa. Sera, Heinsberg, Germany).

Tapeworms of Horses/Equids

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

1. **Name:** Greek: *anoplos* = unarmed; *kephale* = head. Latin: *foliatus* = surrounded

by leaves. The name is related to the leaflike protrusions at the hookless scolex.

2. **Geographic distribution/epidemiology:**

Worldwide, however, importance only in highly infected animals.

Tapeworms of Horses/Equids, Fig. 1 Macrophoto of two adult tapeworms of the genus *Anoplocephala*. They are found contracted in the feces of horses

3. **Morphology/life cycles:**

1. *Anoplocephala perfoliata* This tapeworm reaches a length of up to 25 cm when taken from ileum, caecum or colon, but it shrinks down to 5 cm when found in feces. The scolex (Figs. 1 and 2a, b) is hookless and shows four suckers and four small lobes. The proglottids are significantly broader than long. Intermediate hosts are oribatid mites.
2. *A. magna*. This tapeworm reaches a length of up to 80 cm and its scolex has no lobe-like protrusions.
3. *Paranoplocephala* (syn. *Anaplocephaloides*) *mamillana*: This species reaches only a length of up to 4 cm and a width of 4–6 mm and has slit-like suckers and is rare.
4. **Symptoms of disease:** Mostly low-graded symptoms like disturbances in digestion. However, in infections with huge numbers of worms, the symptoms are as follows: diarrhea, colics, severe weight loss, and intestinal turning.

Tapeworms of Horses/Equids, Fig. 2 Scanning electron micrographs of *Anoplocephala* sp. (a) Anterior end. (b) Scolex LP lobe-like protrusions, SC scolex, SN sucker

Tapeworms of Reptiles and Amphibia

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

5. **Diagnosis:** Microscopical observations of fecal probes show typical eggs (Fig. 3), proglottids, or even total worms. The square-like eggs of *A. perfoliata* and *A. magna* have diameters of 65–80 μm , while those of *A. mammilana* are much smaller (37–51 μm). In low infections, ELISA tests showed about 70 % of the infections.
6. **Infection:** Oral uptake of infected intermediate hosts (e.g., oribatid mites), which contain the typical ► [cysticercoid](#) larvae.
7. **Prophylaxis:** Elimination/reduction of mite numbers in meadow by measurements that decrease humidity in meadow. Repeated changing of the meadows.
8. **Incubation period:** 2 weeks in cases with huge worm masses.
9. **Prepatency:** 4–6 weeks.
10. **Patency:** 6 months.
11. **Therapy:** Praziquantel (1 mg/kg bodyweight) twice a year (June, November).

Adult tapeworms occur in large numbers in the intestine of amphibian and reptiles. Several species are monozoic. They reach in some species up to 1 m in length. However, mostly they are much smaller but may occur in huge numbers. Up to 1,000 tapeworms had been found in larger host animals. In total there exist tapeworms in unbelievable variations. Thus, it is needed to check special literature. Listed here are only a few examples from three orders:

- **Order: Proteocephalidea** – They are diagnosed via their typical eggs (containing the oncosphaera larva in a peculiar embryophore).
- **Order: Pseudophyllidea** – Diagnosis can be done by determination of their operculated eggs, which develop their larval stages in water.
- **Order: Cyclophyllidea** – Diagnosis can be done by detection of proglottids in the feces of their hosts.

Infections with tapeworms may lead to death in cases of huge numbers of parasites. Symptoms are

at the beginning: loss of weight, immobility, and body swellings.

Therapy

The praziquantel-based product Vermol[®] of Fa. Alpha-Biocare (Düsseldorf) has proven to control tapeworm infections in reptiles.

Tapir Nose

Common South American name for ► [cutaneous leishmaniasis](#).

Tarsonemus

Name

Greek: *tarsos* = basis of the foot, *nemo* = filament, hair.

Genus (syn. ► [Acarapis](#)) of the mite family Tarsonemidae, which have long hair at their feet (e.g., ► [Acarapis woodi](#) of the honey bee).

Tau-Fluvalinate

Chemical Class

Pyrethroid (type II, α -CN-pyrethroids).

Mode of Action

Open state voltage-gated sodium channel blocker. ► [Ectoparasitocides: Blockers/Modulators of Voltage-Gated Sodium Channels](#).

Tautonymia

Name

Greek: *tauto* = identical, *onoma* = name.

In the Zoological nomenclature it is possible that genus and species names are identical (e.g., the rat acanthocephalan *Moniliformis moniliformis*), while this is forbidden in Botanical nomenclature.

Taxis

Name

Greek: *taxis* = order.

Taxis describes a type of movement in the direction of, or as a reaction to, a stimulus (positive taxis) or away from such a stimulus (negative taxis), e.g., phototaxis, thigmotaxis, chemotaxis.

Taxon

Name

Greek: *taxon* (pl. *taxa*) = category.

Taxa are ranks, which are given to different groups of related organs due to their characteristics in order to establish a hierarchical ► [classification](#).

TBE

Synonyms

Tick-Borne Encephalitis.

TBF

Thick blood film, malaria diagnosis.

TCA Cycle

Tricarboxylic acid cycle, which is fed by substrates being oxidated in the mitochondrial chain metabolism. Electrons deriving from this cycle are imported into an electron transport chain at the inner mitochondrial membrane. Thus the development of cristate mitochondria is in most cases correlated with an active TCA cycle and the active mitochondrial respiration. ► [Energy Metabolism](#).

TcBat

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes *Trypanosoma cruzi* from bats. As it was seen in paleoepidemiology studies, it is thought to be a plausible ancestor of present *T. cruzi* strains.

Tegument

Synonyms

Neodermis (= new skin).

The syncytial cytoplasmic type of ► [body cover](#) in which giant nuclei or nuclear fragments may occur. It covers the surface of larval ► [platyhelminthes](#) (► [Monogenea](#), ► [Digenea](#), ► [Cestodes](#) and ► [Metazoa](#)) and ► [acanthocephala](#), but the tegument of adult parasitic platyhelminths lacks nuclei (► [Platyhelminthes/Integument](#)).

Tegumental Disks

The ► [tegument](#) of ► [tapeworms](#) is tightly filled with numerous electron-dense-appearing platelets

which are apparently composed of proteins. They are also present in other groups of ► [Platyhelminthes](#), but in lower numbers.

Teladorsagia

Name

Greek: *telos* = end, finish, Latin: *dorsalis* = belonging to the backside.

General Information

Genus of the nematode family Trichostrongylidae. *T. circumcincta* and *T. trifurcata* are mainly placed in the genus ► [Ostertagia](#). They reach as females a length of 12 mm, and 9 mm as males.

Telogonic Ovaries

In most ► [nematodes](#) the ovaries are of the telogonic type where the oogonia are formed in the very tip of the ovary and descend the tube, undergoing the various stages of oogenesis (► [Nematodes/Reproductive Organs](#)).

Related Entry

► [Hologonic Ovaries](#).

Telogonic Testes

The ► [testis](#) of parasitic ► [nematodes](#) belonging to the Secernentae is of the telogonic type, one in which the terminal portion of the testis contains the spermatogonia (► [Nematodes/Reproductive Organs](#)).

Telonymphe

Last stage of scabies-mites, that leaves the skin-channel to copulate on the skin surface. ► [Sarcoptes](#).

TEM

Transmission electron microscopy.

Temephos

Chemical Class

Organophosphorous compounds
(monothiophosphate).

Mode of Action

Acetylcholine esterase inhibitor. ► [Ectoparasiticides: Agonists and Antagonists of Cholinergic Transmission](#).

Tenacity

Name

Latin: *tenacitas* = withstanding.

Resistance of an agent of disease (or a stage of which) against environmental influences, e.g., rate of survival of worm eggs or protozoan cysts when exposed to heat, cold, or dryness.

Tendons

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

► [Insects](#). Latin: *tendo* = sinew, e.g., connecting the segments of the legs of arthropods.

Tergit

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The back shield of the thorax of an insect.

Terminal Cell

Synonyms

Cyrtocyte; Flame Cell.

General Information

The basic component of the protonephritic excretory organs of Platyhelminthes (► [Platyhelminthes/Excretory System](#)) is the terminal cell which is embedded in the ► [parenchyma](#) of the worms. At the basal side, this cell is equipped with typical ► [cilia](#) (► [Platyhelminthes](#), Fig. 24A), the number of which varies between systematic groups and with the size of the developmental stage. These cilia are attached to each other and are surrounded by a circle of finger-like projections of the terminal cell which run along the inner side of the basal lamina (► [Platyhelminthes](#), Fig. 24), which, however, are often missing. The canal cells form a similar ring of protrusions on the outer side of the basement membrane; they stand in the gaps between the inner projections and thus lead to a lattice-like appearance. Ultrafiltration occurs at the basal lamina via the lattice gaps.

The pattern of arrangement and the number of terminal cells is characteristic and may be used for diagnosing species in digeneans, for which flame-cell formula have been established. Adult ► [Dicrocoelium dendriticum](#) worms, for example, have 24 of such cyrtocytes (flame cells)

symmetrically arranged in consecutive sets of 2, and are thus described by the formula $2(2 + 2 + 2 + 2 + 2 + 2) = 24$.

Fine Structure

► [Platyhelminthes](#), Figs. 24 and 25.

Ternidens deminutus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

1. **Name:** Greek (*terna*, end), Latin (*nidificare*, nesting; *deminutus*, becoming smaller at the posterior pole), English (African colon worm).
2. **Geographic distribution/epidemiology:** This nematode occurs in East Africa, in South Africa, and in the countries of the Congo Basin. In some regions many thousands of humans are infected besides monkeys.
3. **Morphology/life cycle:** The adult females measure 12×0.6 mm, while the males are smaller (9×0.5 mm). Both live in the colon mainly of monkeys, but also of humans being attached at the mucous layer by the help of their fortified mouth capsule. The females discharge unembryonated eggs, which measure 60×40 μ m and may easily be misdiagnosed as hookworm eggs. After development inside the eggshell, the larva 1 hatches and grows up via two molts to the infectious larva 3. This stage is orally ingested within contaminated food and reaches via two further molts maturity (♀, ♂) in the colon.
4. **Symptoms of disease:** In general the symptoms of low-graded infections are subclinical.

However, in cases of strong infections, unspecific dysfunctions of the intestine are diagnosed often accompanied by an iron deficiency syndrome and anemia.

5. **Diagnosis:** Microscopic determination of the eggs in feces by help of concentration methods (e.g., flotation; SAFC).
6. **Infection:** Ingestion of infectious larva 3 within contaminated plant food (fruits, salad, etc.).
7. **Prophylaxis:** Use only purely washed plants and fruits for human consumption.
8. **Incubation period:** Unknown (probably 1–2 weeks).
9. **Prepatent period:** Unknown (probably 3–4 weeks).
10. **Patency:** Unknown (probably years due to repeated infections).
11. **Therapy:** See hookworms and *Ancylostoma*.

Tetracapsuloides bryosalmonae

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This species belongs to the phylum ► [Myxozoa](#), class Malacosporea, and causes proliferative kidney disease (PKD) in various species of salmonids (Anderson et al. 1999), which are found in Europe and North America, and can lead to severe losses in rainbow trout (*Oncorhynchus mykiss*) (Walbaum, 1792) and brown trout (*Salmo trutta*) (Linnaeus, 1758) farms. The associated economic losses due to this disease make it an important factor for aquaculture (El-Matbouli and Hoffmann 2002). Additionally, PKD is suspected of contributing to the decline of wild brown trout and salmon populations, especially in Switzerland (Wahli et al. 2002). Spores develop in the kidney

tubules of infected fish and are released via urine to infect freshwater bryozoans (Grabner and El-Matbouli 2008). Proliferation of *T. bryosalmonae* induces granulomatous cellular response in the interstitial tissue which induces swelling of the kidney and spleen.

Tetrachlorvinphos (CVMP)

Chemical Class

Organophosphorous compounds (organophosphate).

Mode of Action

Acetylcholine esterase inhibitor. ► [Ectoparasiticides: Agonists and Antagonists of Cholinergic Transmission](#), Ectoparasitocidal Drugs.

Tetracycline

An antibacterial drug, that is often administered in addition to parasitocidal drugs.

Tetrahymena corlissi

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This species belongs as related ones to the holotrichous ciliates, which normally live free in freshwater. In aquaria, however, these species (about 0.05 mm in length) may settle in wounds, where they are found often in masses. Reproduction occurs in cysts on the ground of the water by binary fission. *T. corlissi* and other ciliates are characterized by their cilia and two differently sized nuclei (Fig. 1).

Treatment: In aquaria the product Protazol[®] by Fa. Sera, Heinsberg, Germany, can be used.

***Tetrahymena corlissi*, Fig. 1** Diagrammatic representation of a trophozoite of *T. corlissi*, which possesses besides the two nuclei also a terminal filament and a large apical cell mouth lined by four rows of cilia

Tetrameres fissipina

Synonyms

Tropisurus fissipinus.

This 6 mm long stomach worm lives in the digestive stomach of duck, chicken, turkey, and dove. Intermediate hosts are: small crustaceans, beetles; the eggs measure 60 × 30 µm.

Tetramethrin

Chemical Class

Pyrethroid (type I).

Mode of Action

Open state voltage-gated sodium channel blocker.

► [Ectoparasiticides: Blockers/Modulators of Voltage-Gated Sodium Channels](#), Ectoparasitocidal Drugs.

Tetramitus

Genus of free-living amoeba related to the genera *Naegleria*, ► [Vahlkampfia](#).

Tetrathyridium

Larva of ► [tapeworms](#) of the family Mesocestoidae (Mesocestoides, ► [Eucestoda](#)), Fig. 1.

***Tetratrichomonas gallinarum*,**

Fig. 1 Diagrammatic representation of two trichomonad species of birds (chicken, doves, turkeys, etc.). Their axostyle appears mostly rather tiny in contrast to that of *Trichomonas* species. Infections with this species introduce diarrheas, light yellow, fluids of cecal origin, often occur with necrosis of the liver and severe loss of weight

Tetratrichomonas Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This genus harbors trichomonad flagellates, which are characterized by four apical free flagella and a recurrent one, which becomes free at the terminal pole. Their ► [axostyle](#) is rather tiny and thus hard to see in stained specimens.

Common species are:

- *T. anatis* of ducks, apathogenic inside the posterior portion of the intestine
- *T. anseris* of geese, apathogenic inside the ceca
- *T. buttreyi* of pigs, opportunistic in the ceca of horses,
- *T. canistomae* of dogs, opportunistic inside the mouth
- *T. felistomae* of cats, opportunistic inside the mouth
- *T. gallinarum* of chicken and turkeys, pathogenic inside the intestine
- *T. ovis* of sheep, opportunistic inside the intestine
- *T. pavlovi* of cattle, apathogenic in the rumen

Texas Fever

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

► [Babesiosis](#), [Animals](#); disease due to tick-transmitted ► [Babesia](#) *bigemina* stages. This

disease was also called redwater fever due to the fact that the urine appears reddish in case of severe infections. The American veterinarians Curtice, Smith, and Kilborne showed in 1893 by an artificial transmission experiment that ticks may be vectors of parasites. In contrast to the name Texas fever, this disease occurs in tropical and subtropical regions of Asia, Africa, America, Australia, and Europe being transmitted by local tick species of the genera *Rhipicephalus* and *Boophilus*.

TGF

Transforming growth factor, which is active in mammalian angiogenesis (also in organ growth due to parasitic infections, e.g., schistosomiasis).

Th

T helper cell.

Th1 Lineages

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

So-called Th1 and Th2 cells are lineages of CD4⁺ T cells. Th1 cells are associated with the development of a cell-mediated immunity against an agent of disease, while Th2 cells are involved in allergic reactions and immune responses to parasitic infections. Th1 and Th2 cells are able to control each other. This, however, may lead to a dominance of one lineage over the other, thus potentially inducing failures in their efficacy.

Thalidomide

Antimicrosporidial Drugs; see treatment of opportunistic agents of diseases.

Thalassemia

Type of genetically derived human blood diseases (α , β -types); the patients with a α -thalassemia, however, profit from a retarded growth of *Plasmodium falciparum* schizonts in red blood cells and thus suffer at a lower degree.

Theiler, Arnold (1867–1936)

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Arnold Theiler arrived in 1891 as young veterinarian in Pretoria (today South Africa). His trip was sponsored by his school comrade Emma Sophie Jegge (1861–1951), which later in 1893 became his wife. After working on a farm (with contact to many animal diseases), he obtained reputation when he organized a vaccine treatment against smallpox in mine workers at the region of the Witwatersrand. Being officially appointed in 1896 as “State Veterinarian for the Zuid-Afrikaansche Republiek,” he succeeded in 1898 in his activity to establish an official Research Institute of Bacteriology. After years of successful scientific work, he founded and became in 1908 the first director of the renowned Onderstepoort Veterinary Institute, which developed vaccines and treatment methods against diseases of animals and humans. Arnold Theiler’s name is honored by using it as genus name for peculiar tick-transmitted blood parasites (► *Theileria*). This naming is based on recognizing his works on *Babesia equi* (now *Theileria equi*) of horses and

especially on papers on *Piroplasma* (now *Theileria*) *parva* of cattle, which leads to the so-called East Coast fever with a death rate of up to 90 %. This disease and the agents of this disease were also studied by ► [Robert Koch](#), who described especially the so-called ray stages in the vector ticks. These stages were later proven by Eberhard Schein (Berlin) and Heinz Mehlhorn (Düsseldorf) as sexual stages in the life cycle of piroplasms (Mehlhorn and Schein 1976, 1984; Mehlhorn et al. 1975). Theiler’s leadership in veterinary science in South Africa was also recognized by the English King George V, when he awarded in 1914 the title “Sir” to Arnold Theiler.

His son Max (1899–1972) and his youngest daughter Gertrud (1897–1986) became also renowned scientists in different fields. Max was awarded in the year 1951 with the Nobel Prize in Physiology or Medicine for his works on the development of a vaccine against the mosquito-transmitted ► [yellow fever](#). His daughter was appointed for a professorship in entomology in South Africa and served for 30 years on the Council for Wildlife Protection.

Theiler, Max (1899–1972)

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The originally Swiss-South African-born scientist Max Theiler is son of the famous Swiss-South

African veterinarian Arnold Theiler. Born in Pretoria (South Africa), he studied Human Medicine in Cape Town and in London (at the famous London School of Tropical Medicine). After being awarded by the M.D., he went to Harvard Medical School and in 1930 to the Rockefeller University in New York, where he stayed until the end of his career. He was awarded in 1951 with the Nobel Prize in Medicine honoring his studies on yellow fever. He showed that this disease (being transmitted by $\rightarrow$ *Aedes* mosquitoes) is not due to an infection with the bacterium *Leptospira icteroides* (now known as agent of the so-called Weil's disease) but due to viruses. Theiler observed that the yellow fever virus introduces encephalitis in mice. However, when transmitting the mouse-borne viruses to rhesus monkeys, immunity was obtained. This finding was the basis for the development by Max Theiler and Hugh Smith (1937) of the so-called 17D vaccine at the Rockefeller Institute, which is still the basis of the yellow fever vaccine of our days.

Theileria luwenshuni

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This species parasitizes in most regions of China in sheep, goats, and cervids being transmitted by *Haemaphysalis quinghaiensis* and *H. longicornis*. This infection endangers several cervid species.

Theileria Species

Jabbar S. Ahmed
Division of Veterinary Infection Biology and
Immunology, Research Centre Borstel,
Programme Priority Infection Biology, Leibniz
Centre for Medicine and Biosciences, Borstel,
Schleswig-Holstein, Germany

Name

The genus name honors the Swiss-South African veterinarian Arnold Theiler (1867–1936). The species names have their origin in Latin: *mutare* = change; *parvus* = small, tiny; *annulus* = ring; *ovis* = sheep; *hircus* = goat; *separare* = dividing from; *equus* = horse; *velum ferrare* = sail-bearing; *orientalis* = belonging to Eastern countries; Greek: *tauros* = bull; Sergeant, Lawrence = family name of the discoverer of a species.

Geographic Distribution/Epidemiology

Worldwide (see Table 1); in Europe occur only a few species of low pathogenicity, while in Africa the relevant species reach killing rates among their vertebrate hosts of up to 90 % or higher (in case these animals are not adapted).

Morphology/Life Cycles

The complete life cycles have been demonstrated in the years 1975–1980 by cooperation of the three German groups of K.T. Friedhoff (Hannover), E. Schein (Berlin), and H. Mehlhorn (Düsseldorf). Robert Koch and coworkers had already described in 1905 the sexual stages (being called “Strahlenkörper” = ray bodies); however, nobody trusted these results until the above-cited groups confirmed Koch's results by experimental transmission, by light and electron microscopy, and by DNA analysis. The life cycles of the *Theileria* species are

Theileria Species, Table 1 Important species of the genus *Theileria*

^aformerly *Babesia equi*

diagrammatically depicted in Figs. 1 and 2. The stages of *T. equi* had been considered to belong to the genus *Babesia* for long until the reproduction inside lymphocytes had been proven by the groups of Schein and Mehlhorn. Robert Koch's ray bodies are now included as female and male gametocytes (= gamonts) and gametes. Male and female gametes fuse and give rise to a zygote, which stretches and increases in length (as it is the case in ► *Plasmodium* zygotes). In contrast to the stages in ► *Plasmodium* species, which were called ► ookinetes, the stages in the *Theileria* species were just called ► kinetes. Also in contrast to the ► *Plasmodium* species (which form an oocyst at the outer side of the intestine of the mosquito), the *Theileria* kinetes leave the

intestine and enter directly the cells of the salivary glands, where they start formation of sporozoites. They exclusively enter the salivary glands, while ► *Babesia* kinetes also enter other cells including the eggs inside the ovaries of females.

After transmission by ticks, the sporozoites of *Theileria* species enter the lymphocytes of their vertebrate hosts. There, they grow up at first to so-called macroschizonts, which induce the host cells to permanently repeated divisions, whereby also the macroschizonts are divided (Figs. 3 and 4). The macroschizonts are also called Koch's spheres or Koch's bodies honoring their discoverer. Finally, when merozoite reproduction starts, a new generation of schizonts (microschizonts) is formed (Fig. 4). As soon as these merozoites are

Theileria Species, Fig. 1 Diagrammatic representation of the *Theileria* species of ruminants (for hosts see Table 1). 1 Sporozoites are injected during blood meal of ixodid ticks. 2 Schizont (Koch's body) inside the cytoplasm of newly dividing lymphocyte, eventually forming merozoites. 3 Free motile merozoites enter erythrocytes. 4 Binary fission inside erythrocyte (at a low rate). 5 A few free merozoites enter other erythrocytes. 6 Formation of spherical or ovoid stages (i.e., gamonts). 7, 8 Gamonts free in blood masses inside tick gut. 8.1–8.4 Formation of four-nucleate microgamonts (8.2) which give rise by fission to uninucleate microgametes (8.3–8.4). The latter fuse with the macrogamete (9). 9 Macrogamete. 10 Zygote. 11–13 Formation of motile kinete from ovoid immobile zygote inside intestinal cells of the tick.

Note that the developing kinete protrudes into an enlarging vacuole (IV) within the zygote. In *T. parva* kinetes (13) division of the nucleus may start before they leave the intestinal cells. 14 After molt of the ixodid tick and attachment to a new host, kinetes enter the cytoplasm of cells of salivary glands, and give rise to young sporonts which grow and initiate repeated nuclear divisions. 15 Parasitism leads to considerable enlargement of the host cell and its nucleus. Inside the giant host cell the sporont forms thousands of sporozoites. The latter become transmitted during the next blood meal. AV alveolar cell of salivary glands; BI binary fission; E erythrocyte; IV inner vacuole; KB Koch's body (= schizont); N nucleus; NH nucleus of the host cell; SP sporozoite; SPO sporont; TH thorn-like structure; YS young sporont (From Mehlhorn and Schein 1984)

Theileria Species, Fig. 2 Diagrammatic representation of the life cycle of *Theileria equi* (formerly *Babesia equi*). 1 Sporozoite injected with tick (nymph, adult female) saliva. 2 Young schizont in a lymphocyte (macroschizont, Koch's body). 3 Late schizont in a lymphocyte during the formation of merozoites (microschizont). 4 Free ► **merozoite**. 5 Reproduction inside erythrocytes – note the occurrence of Maltese cross-like dividing stages and the presence of spherical stages (gamonts). 6 After engorgement of ticks the ovoid/spherical gamonts undergo further development within the blood masses inside the intestine (mostly inside host cells). 7–10 By divisions some raylike microgametes (10) are produced by microgamonts (7, 8). 11 Fusion (► **syngamy**) of gametes. 12–16 Inside the

zygote (12) a slender, motile, club-shaped ► **kinete** is developed, which leaves the intestinal cells and enters via hemolymph the salivary gland cells of the ticks after their moult (larva nymph adult female) and their attachment to another host. 17 Penetrated kinetes grow up inside the salivary gland cells and give rise to multinucleated sporonts. 18 The multinucleated sporonts are divided into numerous small sporoblasts (SB) which form sporozoites by a budding process at their periphery; during the next sucking period the sporozoites are injected (with the saliva) to the new host. G ► **gamont**; IV inner vacuole; M microschizont; N nucleus; NH nucleus of the host cell; S sporozoite; SB ► **sporoblast**; SP sporonts (From Mehlhorn and Schein 1998)

Theileria Species, Fig. 3 *Theileria* schizonts: Light micrograph of a Giemsa stained smear preparation of lymphocytes containing macroschizonts (= Koch's bodies, upper half) and microschizonts with merozoites (below) around disrupted lymphocytes

Theileria Species, Fig. 4 Transmission electron micrograph of a section through a lymphocyte containing a macroschizont (= Koch's bodies, above) and a schizont during formation of merozoites (below = microschizont) (From Mehlhorn and Schein 1984)

mature, the lymphocytes are ruptured; the merozoites are set free (Fig. 3) and enter red blood cells (Figs. 1, 2, 5, 6, 7, and 8), where they start reproduction by binary fissions. This reproduction leads to several parasites inside the red blood cells, which finally rupture and release the merozoites, which

Theileria Species, Fig. 5 Light micrograph of a Giemsa-stained smear preparation containing erythrocytes with developing stages of *Theileria annulata*

Theileria Species, Fig. 6 Light micrograph of a Giemsa-stained smear preparation of *Theileria parva*

enter new erythrocytes. During penetration, they are enclosed within a parasitophorous vacuole inside their host cell. Later, the merozoites of *Theileria* and *Babesia* species are situated directly inside the cytoplasm of the red blood cell, since the parasitophorous membrane at first formed becomes dissolved (Figs. 8, 9).

Important Species

In Cattle and Buffaloes

- *T. mutans*, the agent of the so-called mild theileriosis or pseudocoast fever in Africa.

Theileria Species,

Fig. 7 Diagrammatic representation of developmental stages of the genera *Theileria* and *Babesia*. (a) *Babesia bigemina*: intraerythrocytic merozoite (3–5 µm). (b) *Theileria* sp.: merozoite, sporozoite in saliva or lymph (1–2 µm). (c) *Theileria* sp.: erythrocytic merozoite (1–1.5 µm). (d) *Theileria* sp.: microgamont = ray body inside the intestine of ticks (5–10 µm). (e) *Theileria* sp. and *Babesia* sp.: kinete (~ up to 20 µm). (f–i) Blood smear preparations: (f) *B. bigemina*; (g) *B. bovis*; (h) *B. divergens*; (i) *Theileria* merozoite and gamont. DW double-walled organelle (mitochondrion); ER endoplasmic reticulum; ES thorn; FO flagellum-like protrusion; MN micropore; MT microtubules; N nucleus; NV food vacuole; P polar ring; PE pellicle; PP posterior polar ring; SB accumulation of micronemes inside a vacuole; UL underlying material; V vacuole; ZM cell membrane (From Mehlhorn and Schein 1984)

Their intraerythrocytic stages are mostly spherical and reach a diameter of about 1.5 µm. Vectors are tick species of the genus *Amblyomma*.

- *T. parva*, the agent of the East Coast fever in Africa (Figs. 7 and 8). This species is extremely pathogenic with mortality rates of up to 90 %. Vectors are ► *Rhipicephalus* ticks (e.g., *R. appendiculatus*).
- *T. parva lawrenci*, the agent of the ► **corridor disease**, which occurs in Africa, south of the Sahara. Vectors are ticks, e.g., *Rhipicephalus appendiculatus*.
- *T. annulata*, the agent of the Mediterranean Coast fever (Fig. 9), which occurs in North Africa, in the Near and Middle East, as well as in Central Asia.
- *T. orientalis* (syn. *T. sergenti*), the agent of the Oriental theileriosis. Vectors are species of the tick genus *Haemaphysalis*.
- *T. orientalis*, the agent of the Asiatic or Asian theileriosis, which is transmitted by ► *Haemaphysalis longicornis* in Japan and South and East Asia.
- *T. taurotragi* (syn. *Cytauxzoon taurotragi*), the agent of the second form of the pseudocoast

Theileria Species,

Fig. 8 Diagrammatic representation of a longitudinal and a cross section of a gamete of *Theileria parva* in the intestine of the vector tick. After fusion of two apparently sexually different gametes a zygote is formed, which becomes finally transformed into a kinete, which leaves the intestine and enters the salivary glands, where sporozoites are produced. *ES* thorn; *LM* limiting membrane; *LS* labyrinthine structure; *MI* mitochondrion; *MT* microtubule; *MTZ* microtubules interrupted due to design; *N* nucleus; *PT* protrusion; *V* vacuole (From Mehlhorn and Schein 1984)

fever, which is transmitted by *Rhipicephalus* ticks in Africa.

- *T. velifera*, which seems to be apathogenic but needs to be excluded before starting any theileriosis treatment. It is transmitted by *Ambylomma* ticks in Africa.

In Goats and Sheep

- *T. ovis*, this agent of the apparently apathogenic “sheep theileriosis” represents probably a broad spectrum of similar-looking subspecies or strains. The stages are mostly rather tiny (~1.3 µm), but they introduce malformation of the parasitized erythrocytes, which finally appear polymorphous. Vectors are ticks of the genera *Rhipicephalus* and *Haemaphysalis*. Apparently, ► *Ixodes species*

should be able to transmit *T. ovis*, too, since double infection with *Babesia motasi* are found.

- *T. hirci*, the agent of the “goat theileriosis” in Southern Europe and Africa. While the stages in the erythrocytes have only diameters of 2 µm, the schizonts in the lymphocytes reach a size of up to 20 µm. Vectors are ticks of the genus ► *Hyalomma*.

In Horses and Other Equids

- *Theileria* (syn. *Babesia*) *equi*. This species, which is now introduced into the genus *Theileria* (as result of the detection of schizonts and merozoites inside lymphocytes, Fig. 15), occurs in Southern Europe, Africa, Asia, and America. The merozoites reach a length of

Theileria Species, Fig. 9 Diagrammatic representation of a longitudinal and a cross section (a, b) of a four-nucleated microgamont of *Theileria parva* in the tick. This stage gives rise during division to four uni-nucleated gametes (which might be female or male). These stages as well as their uni-nuclear progeny had been called by Robert Koch “Strahlenkörper” (= ray bodies). *D* dense body; *DW* double walled vesicle (mitochondrion); *ES* thorn; *FB* filamentous structure; *LS* labyrinthine structure; *MT* microtubule; *MTZ* microtubules interrupted in design; *N* nucleus; *PN* perinuclear space; *PT* protrusion; *RI* ribosomes; *UM* sell membrane; *VS* fortifying structure (From Mehlhorn and Schein 1984)

1.5–2 μm and are reproduced not only by binary fission but also by simultaneous division into four stages, which remain connected at their posterior pole, thus appearing together like a so-called Maltese cross (see ► *Babesia* species of horses). Vectors are specimens of the tick genus ► *Hyalomma* or the species *Rhipicephalus evertsi*. Inside female ticks, there is no transmission of infectious stages

into the eggs. This corresponds to the procedures in all *Theileria* species. This is another supporting criterion to exclude this species from the genus *Babesia*, wherein general infectious kinetes enter the eggs inside the ovary of the females.

A certain amount of the erythrocytic stages develop into gamonts and are later transformed inside the tick's intestine into ray bodies = gamonts, gametes (Fig. 1).

Symptoms of Disease (Theileriosis)

In infections with the pathogenic species, the first symptoms start about 7 days after attachment of infected ticks at the skin of their hosts. These high-shivering fits (up to 41.5 °C) are due to the formation of numerous schizonts inside lymphocytes, which thus become disrupted. These fevers are accompanied by heavy swellings of the lymph nodes and the spleen. During this phase (especially in African species), high death rates may occur before merozoites can be diagnosed in Giemsa stained blood smear preparations. If this phase is survived, the erythrocytes become infected and show the typical stages (Figs. 5 and 6), which are situated directly inside the cytoplasm of the erythrocytes as can be seen on transmission electron micrographs (Figs. 8 and 9). During this phase of reproduction inside the erythrocytes, the following symptoms occur: anemia, icterus and in some cases hemoglobinuria (up to blackish urine), weakness, loss of weight, and death in severe cases. Species with low pathogenicity show low-graded symptoms (e.g., retarded growth, reduced blood uptake, low-graded motility, loss of fitness) or medium symptoms (such as fevers, breathlessness, laying on the ground, etc.). **Attention:** *Theileria* infections often induce immunosuppression (Figs. 10 and 11).

Diagnosis

During the phase of the infection of lymph nodes, diagnosis can be done by microscopic inspection

Theileria Species, Fig. 10 Diagrammatic representation of the development of motile babesian and theilerian kinetes from a spherical zygote. (a) Zygote. (b) Early stage of a kinete, which grows into an inner vacuole. (c) Nearly fully grown kinete still inside the zygote. (d) Final motile kinete. *DK* dense granules; *DW* double walled vesicle; *FB* fibrillar body; *IIM* interruption of inner membrane;

IM inner membrane; *LM* limiting cell membrane; *LV* limiting membrane of an inner growing vacuole; *MN* micronemes; *N* nucleus; *OM* outer membrane; *P* polar ring; *PE* pellicle; *PP* posterior polar ring; *RB* residual body; *V* vacuole; *ZY* zygote (From Mehlhorn and Schein 1984)

of Giemsa stained smear preparations of material, which is obtained by puncture of the lymph nodes. The macroschizonts (also called Koch's bodies) are easily visible (Fig. 4). Starting from the 10th day p.i., the intraerythrocytic stages occur in low numbers, which, however, are constantly increased (Figs. 6 and 7).

Infection

Percutaneous injection during bites of specific ► ticks of various species (see Table 1).

Prophylaxis

Regular protection of cattle and other hosts by use of acaricides in different products and application forms (e.g., dipping, spraying, collars for dogs). In some cases, vaccination with attenuated strains is possible; however, it should be avoided to inject such vaccines into immunocompromised animals, since otherwise infection would start immediately.

Incubation Period (in Pathogenic Species)

About 5–7 days.

Theileria Species,

Fig. 11 Reproduction of a plate containing stages of *Theileria parva* inside the vector tick (no 9–11) and in lymph nodes of cattle (no 47–49) painted 1905 by Robert Koch and his coworker Kleine on occasion of an expedition to East Africa. The stages 9–11 represent the so-called ray bodies (gametes before or after fusion), while Figs. 47–49 show so-called Koch's bodies (= macroschizonts, next to the large dense nucleus) in the lymphocytes of cattle. Figure 47 shows a macroschizont after disruption of the host cell and some non-infected red blood cells. In Figs. 48 and 49 several red blood cells already contain the comma-shaped merozoites. Some of them will later develop into ray bodies (= gamonts, gametes) (depicted in Figs. 9, 10, and 11) (Table drawn by members of the group of Nobel Prize winner Robert Koch in the year 1915)

**Prepatent Periods**

About 5 days after infection by ticks, schizonts may appear in the lymphocytes.

Patency

Years in cases of species with reduced pathogenicity or after survival of infections with pathogenic species.

Therapy

Application of chemotherapeutic compounds introduces high toxicity risks. Therefore, diagnosis must be absolutely sure!

Cattle

- (a) **Parvaquone** = Clexon[®] = solution to inject intramuscularly. Total dose: 20 mg parvaquone/kg body weight given in two doses of 10 mg at a 48 h interval.

- (b) **Buparvaquone** (Butalex[®], Pittman-Moore):
1 × 2.5 mg/kg body weight.
- (c) **Halofuginone** = Terit[®]: Total dose 2 mg/kg body weight to apply orally: 2 × 1 mg/kg body weight at an interval of 48 h. The dose is mixed into 500 ml water before application.

Horses

- (a) **Imidocarb** is recommended to treat horses in the case of *T. equi*.

Theileriacidal Drugs

For overview see Table 1 (page 1367 et sqq.).

Epizootiology

The ► [piroplasm](#)s are tick-transmitted blood cell parasites of vertebrates occurring in lymphocytes, erythrocytes, and other blood system cells (► [Theileria](#)). The occurrence of vectors (► [Ticks](#)) determines the geographical distribution of *Theileria* spp. in tropical and subtropical areas.

T. parva parva causing East Coast fever (ECF) is enzootic in South, East, and Central Africa and may be lethal for *Bos taurus*, *B. indicus*, and *Bubalus bubalis* (water buffalo) as well as for imported cattle. *T. p. lawrencei* causing ► [corridor disease](#) occurs primarily in African buffalo (*Syncaerus caffer*) and is endemic in East and Central Africa and Angola as well. It may produce a mild disease in buffalo but a fatal one in cattle and water buffalo. *T. annulata* causing tropical ► [theileriosis](#) occurs in the northern subtropical and Mediterranean regions from Morocco through the Middle East, southern region of Russia, and neighboring countries to the Indian subcontinent and China. It may be lethal to cattle but may produce only mild disease in buffalo. *T. orientalis* (syn. *T. sergenti*) has a low to moderate pathogenicity, and its distribution coincides over large areas of Asia with that of *T. annulata*. *T. mutans* regarded as mildly pathogenic or nonpathogenic may be severely pathogenic in cattle under various stress situations; this species is ubiquitous. *T. hirci* and *T. ovis* may be common in sheep and goats. *T. hirci* occurs in Asia, Africa, and South Europe and may cause a

severe disease (50–100 % mortality), mainly in newly introduced animals. Its morphology is similar to that of *T. annulata*. *T. ovis* has a low pathogenicity and is morphologically indistinguishable from *T. hirci*. However, *T. ovis* is more widely distributed than *T. hirci* and occurs in Africa, Europe, parts of the former USSR, India, and West Asia.

Strategic Control Programs

Strategic control programs used in enzootic areas with ► [theileriasis](#) in livestock are similar to that applied in babesiasis (► [Babesiacidal Drugs](#)). They rely on measures, such as premunization (live, attenuated vaccines, or “infection-treatment”), tick control (regular acaricide dipping, other application techniques), quarantine (especially with regard to importation of cattle from *Theileria*-free areas into enzootic regions where tick vectors exist), ► [chemoprophylaxis](#), and finally chemotherapy.

To prevent cattle from areas and farms contaminated with infected ticks stock-proof fencing is essential. Therefore, the farm area must be cleaned of infected ticks before susceptible animals are brought in, and at least weekly dipping (in case of *Rhipicephalus appendiculatus* at least two treatments per week) should be carried out to control *T. p. parva* infections. Enzootic stability as a means of controlling theileriasis (as partially practiced in controlling babesiasis) may be achieved by natural challenge in indigenous cattle and thus development of some degree of resistance against theileriosis. Stock recently introduced into infested areas and coming from regions free of *Theileria* spp. or areas with different strains of *Theileria* spp. may need, however, a year longer for partial immunity to be developed by application of various vaccination schemes. Tetracyclines (Table 1) are mainly used in chemoimmunization programs (infection-treatment methods). They may suppress or eliminate infections in areas where cattle have already developed a certain degree of protective immunity against *T. p. parva* and *T. annulata*. Tetracyclines administered simultaneously with infected ticks

Theileriacidal Drugs, Table 1 Antitheilerial drugs for use in cattle

Chemical group nonproprietary name (single dose mg/kg body weight = b.w.)	*Brand names (manufacturer, companies, distributors), WT (in days = d) before slaughter, other information	Comments on efficacy, pharmacokinetics, metabolism, mode of action, toxicity, and other information
Theileriosis, caused by <i>Theileria</i> spp. is a cattle disease transmitted by various ticks (e.g., brown ear tick <i>Rhipicephalus appendiculatus</i> transmitted <i>T. parva</i> causing East Coast fever = ECF and Corridor disease); ECF is widespread in several countries in eastern, central, and southern Africa; efficacy of chemotherapy depends on early and fast diagnosis; treatment should be given in the early stages of clinical disease; after the onset of respiratory symptoms none of the chemotherapeutic agents is effective any more; recovered animals can remain carriers of the parasite; the disease results in inevitable costs for cattle keepers, either by losses in productivity (mortality, morbidity) or by expenditures for disease and/or vector control [for details cf. D'Haese L. et al. (1999) Trop Med and Int Health 4: 49–57]		
Tetracyclines (first practical use of chlortetracycline 1953)		
Oxytetracycline (OTC) hydrochloride or dehydrate (= base) (11–20 i.m. cattle, calves) <i>approved indications</i> : bacteria, <i>Mycoplasma</i> , chlamydia, and rickettsiae, <i>Anaplasma</i> spp	*Terramycin LA (Pfizer, USA, Australia, EC, elsewhere), injectable solution for cattle, calves, WT: USA 15 days; Australia WT: 42 days (OTC base in 2-pyrrolidone); EC/Germany WT: 21 day	Theileriosis is a severe disease of cattle in Africa; the disease has severe depressant effects on immune system; therefore, any vaccination should be delayed until animals have recovered; in experimental studies Neitz (Onderstepoort, University Pretoria, SA) had demonstrated in 1953 that chlortetracycline HCl (CTC) was able to prevent clinical signs of theileriosis (ECF) in cattle when treatment was started 1 day prior to or simultaneously with <i>Theileria parva</i> (<i>T. parva parva</i>) challenge (oral dose regimen: 1.5 mg/kg b.w. daily for 28 days); effective plasma drug levels during incubation period are necessary to arrest schizogony of <i>Theileria</i> in lymphoid cells and reduce parasitemia (merozoites in erythrocytes); OTC may be used in preventive chemoimmunization programs aimed at supporting the development of a premunition type immunity in cattle herds against <i>Theileria</i> challenges in endemic areas; an immunization procedure used for ECF may be Radley's "Infection and Treatment method" whereby a titrated (attenuated) sporozoite stablate of infected ticks is injected simultaneously with a 20 mg/kg b.w. dose of long-acting tetracyclines; selection of the immunizing stock(s) of <i>T. parva</i> should ensure that cattle are immunized against subsequent field challenges with all <i>T. parva</i> stocks in the area; so treated animals usually remain carriers of the parasite since long-acting formulations of OTC suppress but do not eliminate all organism at the schizont stage; OTC base in pyrrolidone (*Terramycin

(continued)

Theileriacidal Drugs, Table 1 (continued)

Chemical group nonproprietary name (single dose mg/kg body weight = b.w.)	*Brand names (manufacturer, companies, distributors), WT (in days = d) before slaughter, other information	Comments on efficacy, pharmacokinetics, metabolism, mode of action, toxicity, and other information
		LA) is designed to give long duration effective plasma drug concentrations, e.g., a single injection supplies 3–5 days “therapeutic” cover and can be repeated if necessary; OTC appears to be concentrated in the liver and is excreted in the bile; it is found in the urine and feces in high concentrations in a biological active form; <i>anaplasmosis</i> is a hemotropic disease of cattle (transmitted by ticks) and may hamper development of livestock industry; tetracyclines such as CTC and OTC are equally effective, and low numbers of <i>Anaplasma</i> in carriers can be eliminated by the 2 tetracyclines; vaccination with attenuated <i>Anaplasma</i> vaccines and chemotherapy with tetracyclines or a combination of the 2 are aimed at controlling the disease in tropical and subtropical areas; premunition type immunity may also exist in <i>Anaplasma</i> infected cattle (cf. <i>Theileria</i> ↑); carrier state of low numbers of the organism may serve to propagate the spread of organisms; it allows long-lasting buildup of premunition-immunity that may prevent heavy outbreaks of the disease in cattle herds
Hydroxynaphthoquinones		
Menoctone is a hydroxy alkylated naphthoquinone (experimental studies mid/end 1970s, Wellcome Research Laboratories); it has not been developed as a commercial product because its synthesis was too expensive; it controlled theileriosis in cattle caused by <i>T. parva</i> at a single i.m. or i.v. dose of 10 mg/kg b.w. up to 4 days after the disease became apparent; the oral route of menoctone had only a slight and transient beneficial effect; the drug caused degeneration of schizonts in lymphoid cells, and merozoites in red cells (piroplasms) were destroyed; intramuscular injection of the drug produced severe but transient pain; menoctone was replaced by parvaquone (= PVQ, BW 993, introduced in Kenya 1985, it has been commercialized as *Clexon and then as *Parvexon); it was selected as the most cost-effective compound from a series of naphthoquinones; its antitheilerial activity is inferior to that of menoctone; there is no apparent discomfort after deep i.m. injection; occasionally, localized “painless” edematous swelling occurred; PVQ is sufficiently active against <i>T. parva</i> and <i>T. annulata</i> infections in the field if used in the early stage of infection (macroschizonts detectable, fever starts); PVQ is liable to eliminate stabilate infection of <i>T. parva</i> when the sporozoite stabilate and the drug is injected simultaneously; *Clexon/*Parvexon therefore is unsuitable for use in a single-treatment infection-and-treatment system of immunization; recommended dose regimen: single dose of 20 mg PVQ/kg b.w. i.m. for cattle infected with <i>T. annulata</i>, and 10 mg PVQ/kg b.w. i.m. twice (48 h interval) for cattle infected with <i>T. parva</i>, <i>T. parva lawrencei</i> (Corridor disease) and <i>T. mutans</i> (benign African theileriosis)		
Buparvaquone (BW 720 C) (BPQ) (2.5, i.m. cattle single dose; in severe cases a further treatment with BPQ, at same dose rate of 1 ml/20 kg b.w. =	*Butalex (various manufacturers and suppliers, e.g., ICI Pakistan: (rights from Schering Plough), Coopers AH UK, solution for i.m. injection (50 mg BPQ/ml), WT: 42?; BPQ +	Synthesis of BPQ is much more expensive than that of PVQ; it is an analogue of PVQ with long persistence in plasma following i.m. injection (half-life at least

		might be due to difference between parasite and mammalian ubiquinone moiety; approved indications: for treatment of theileriosis [ECF caused by <i>T. p. parva</i> , Corridor disease: <i>T. p. lawrencei</i> , and tropical theileriosis: <i>T. annulata</i> and <i>T. orientalis</i> (syn. <i>T. sergenti</i>)]; BPQ is active against both schizont and piroplasms stages of <i>Theileria</i> and should be used in incubation period of the disease, or at the latest when first clinical signs are apparent; limitations: *Butalex must not be given by intravenous or subcutaneous injection; regular injection into muscles of the neck may occasionally cause localized, painless, edematous swelling; repeat treatment in cases of severe theileriosis (relapse), or when relapses occur as a result of subsequent infections with antigenically unrelated species or strains of <i>Theileria</i> (animals will develop homologous immunity only); any vaccination should be delayed until animal has recovered from theileriosis (the disease suppresses immune system)

Quinazolinones

Halofuginone lactate (= HAL), introduced 1986 in Kenya, first available as *Lerioxine, and then *Terit (former Hoechst Roussel Vet., oral tablets, aqueous solution); HAL is no longer approved for use against theileriosis caused by pathogen *Theileria* spp. in cattle; *Terit has been discontinued possibly because of little commercial return for minor uses in a major species; HAL (1.2 mg/kg b.w. per os and repeated after 48 h) manifested a potent effect on schizonts of natural *T. parva* infections in cattle between 5 and 11 days post treatment; disappearance of piroplasms (erythrocytic stages) took long, ranging from 1 week to 1 month following treatment; recommended treatment during acute clinical disease induced by *T. parva* isolates in cattle rapidly reduced fever and parasitosis but parasite recrudescences and mortality occurred in about 50 % of treated animals within 15 months after treatment; because HAL showed only moderate action on erythrocytic forms recovered animals usually remained carriers of the parasite; a potent activity of HAL was seen when treatment of *T. annulata* and *T. parva* infected cattle was started with first clinical signs (body temperature above 40 °C) and macroschizonts were detectable by lymph node biopsies; it was less active when administered during incubation period; recovered animals were then carriers; in a field trial in Kenya, 293 cattle suffering from ECF were treated at a dose of 1.2 mg/kg b.w. per os and treatment was repeated after 48 h: 236 (80.5 %) animals recovered and 49 (16.7 %) died; there were no differences in recovery rates between uncomplicated cases with concurrent anaplasmosis or babesiosis; younger animals had a poorer recovery rate than adults and early treatments were more successful than those administered late; it was concluded that with early detection and treatment, coupled with efficient tick control HAL is effective in treatment of clinical ECF under field conditions; **tolerability** of HAL at recommended dose regimen is good but safety margin is narrow; 3 mg/kg may cause subnormal temperature, profuse diarrhea, cachexia, and purulent eye discharge; cattle preslaughter withdrawal periods for milk/edible tissues were 8/24 days

(continued)

Theileriacidal Drugs, Table 1 (continued)

Chemical group nonproprietary name (single dose mg/kg body weight = b.w.)	*Brand names (manufacturer, companies, distributors), WT (in days = d) before slaughter, other information	Comments on efficacy, pharmacokinetics, metabolism, mode of action, toxicity, and other information
---	--	---

HAL is now commercialized as *Halocur: **approved indication** in EC: for prevention of diarrhea caused by *Cryptosporidium parvum* in newborn calves on farms with a history of cryptosporidiosis and reduction of diarrhea due to diagnosed *Cryptosporidium parvum*. *Halocur has been demonstrated to reduce oocyst excretion; **drug/dose form**: pale yellow solution for oral administration containing 0.5 mg HAL/mL in aqueous excipient for oral use in calves **after feeding**; WT: calves, meat and offal 13 days; **dose regimen**: 0.08–0.13 mg HAL/kg b.w. once a day for 7 consecutive days (calves 35–45 kg b.w.: 8 mL *Halocur and calves 45–60 kg b.w.: 12 mL *Halocur once a day for 7 consecutive days); **toxicity** may occur at two times the recommended dose; animals should therefore receive accurate dose; adverse effects following overdose may be diarrhea, visible blood in feces, decline in milk consumption, dehydration, apathy and prostration; HAL proved also active against acute *sarcosporidiosis* in goats (*Sarcocystis capracanis*) and sheep (*S. oivicanis*, syn. *S. tenella*) at 0.67 mg/kg daily for 2 days (for data concerning anticoccidial activity of halofuginone bromide cf. ► **Coccidiocidal Drugs**/Table 1)

Data of drug products (approved labels) listed in this table refer to information from literature, manufacturer, supplier, and websites such as the European Medicines Agency (EMA), Committee for Veterinary Medicinal Products (CVMP), the US Food and Drug Administration (FDA), Center for Veterinary Medicine (CVM), the Australian Pesticides and Veterinary Medicines Authority (APVMA) and associated Infopest (search for products), VETIDATA, Leipzig, Germany, and Clini Pharm, Clini Tox (CPT), Zurich, Switzerland and others
Data given in this table have no claim to full information.

or vaccines can modify the course of the infection so that proliferation of parasites is limited and allow the development of protective immunity. As a result of infection-treatment methods mild clinical symptoms may occur while immunity is built up in the host. Another successful method of immunization against ECF seems to be the infection of cattle with live sporozoites (derived from standardized stabulates of *Rhipicephalus appendiculatus* followed by the administration of a long-acting oxytetracycline (cf. Table 1). Although treated animals showed a solid resistance to homologous challenge, they were not protected against a challenge with parasites unrelated to those initiating the primary reaction. To overcome this very specific immune responses, so called “cocktail” vaccines derived from different strains have been prepared and used in large-scale field trials of immunization against cattle theileriosis. A satisfactory ► **schizont** vaccine against *T. annulata* does not require simultaneous drug treatment, and so saves costs.

Economic Importance and Pathogenesis

There are several *Theileria* spp. with different pathogenic features (► **Theileriosis**). Parasites of

economic importance in cattle are *T. p. parva* and *T. p. lawrencei*, which cause East Coast fever (ECF) and corridor disease, respectively, as well as *T. annulata*, which produces tropical theileriosis. Commercial dairy herds and high-performance beef cattle on pastures must be protected against these *Theileria* spp. since their pathogenicity is generally high. Thus, mortality in fully susceptible cattle infected with *T. p. parva* may reach 90–100 % although fatal cases in all are lower in endemic areas, and zebu cattle commonly show a high level of ► **natural resistance**. Fatal infections caused by *T. annulata* in cattle may vary considerably (10–90 %). Under natural conditions the interaction between host and parasite depends on host susceptibility, age, and variations in virulence of *Theileria* spp. strains, and intensity of challenge, i.e., the number of parasites transmitted by total number of ticks. The course of infection may therefore vary from peracute, acute, or subacute, to chronic, although the acute form is the usual one in susceptible animals (calves are more resistant to infection). Clinical signs in the acute and subacute forms are high to irregular intermittent fever, markedly swollen (enlarged) lymph nodes (► **Hyperplasia**), edema, ► **diarrhoea**, dyspnea, anemia, leukopenia (below 1000 cells/mm³ is fatal in most cases), and general

weakness. The pathogenesis and clinical symptoms are associated with the multiplication of parasites within transformed lymphoblastoid cells. Damaging effects on lymphoid tissues follows repeated ► [schizogony](#) synchronized with division of host cells. The lymphodestructive processes are characteristic for infections with *T. p. parva*, *T. annulata*, and *T. hirci*, while *T. orientalis* (syn. *T. sergenti*) and *T. mutans* infections are associated with invasion and destruction of erythrocytes resulting in anemia. Animals that recover from lymphoproliferative theileriosis have usually eliminated macroschizont stages and are solidly resistant to homologous challenge; however, challenge with heterologous parasites may lead to a partial or complete breakdown of immunity.

Drugs Acting on Theileriasis and Theileriosis

For a long time the search for an active drug was hampered by the lack of a suitable laboratory model of the infection. Chlortetracycline was shown to be the only drug, which exhibited prophylactic activity on *T. p. parva* infections. Today, long-acting oxytetracyclines are used which may arrest development of parasites in lymphocytes and thus reduce the rate of invasion of the cells (Table 1). To exhibit a reliable action tetracyclines must be given simultaneously with the initial *Theileria* spp. infection. As a result they curtail clinical symptoms in susceptible cattle types and consolidate immunity to virulent *Theileria* spp. strains; tetracyclines cannot be used for curative treatment and are ineffective once clinical signs become evident.

A high level of antitheilerial activity of **menoctone** [2-hydroxy-3-(8-cyclohexyloctyl)-1,4-naphthoquinone] was demonstrated by several investigators in *T. parva*-infected bovine lymphoid cell cultures. Subsequent tests in cattle artificially infected with *T. p. parva* confirmed the activity of menoctone against East Coast fever (ECF), even in cases with already established infection. Prior to the discovery of the antitheilerial effect hydroxynaphthoquinones had been shown to be active against ► [coccidia](#)

and ► [malaria](#) parasites; recently, **atovaquone** (► [Malariacidal Drugs/Tables 1, 2](#)) has also been proved to exhibit a high antiplasmodial activity. Menoctone was then replaced by the closely related analogue **parvaquone**, which has a lower activity but is better tolerated by cattle than menoctone. The most active antitheilerial compound in the hydroxynaphthoquinone series is **buparvaquone**; it has been shown to be distinctly more active than parvaquone (Table 1). Like the quinazolinone derivative **halofuginone lactate** (no longer available for this indication; anticoccidial effect of the bromide salt cf. ► [Coccidiocidal Drugs/](#)Table 1) both drugs are effective in treating the early stages of *T. p. parva* and *T. annulata* infections. Once established neither halofuginone nor parvaquone or buparvaquone can sterilize *Theileria* spp. infections. Prophylactic administration of hydroxynaphthoquinones obviously prevents infection completely and thus development of any serological/immunological response. Treated cattle were fully susceptible to a later *T. p. parva* challenge. The use of halofuginone lactate in the treatment of ECF in Tanzania had certain limitations. Field studies revealed that losses from theileriosis could be prevented only following diagnosis of early cases of the disease in several herds by repeated oral administration of 1.2 mg/kg b.w. Cattle suffering from the early stages of ECF recovered completely after this dosage regimen whereas two out of six cattle treated in the late stages died. **Imidocarb** dipropionate (► [Babesiocidal Drugs/](#)Table 1) and **primaquine** diphosphate (antimalarial, cf. ► [Malariacidal Drugs/Tables 1, 2](#)) have been shown to be effective in reducing *T. orientalis* (syn. *T. sergenti*) parasitemiae in cattle at doses of 1.2 mg/kg b.w. ($\times 1$) and 1 mg/kg b.w. ($\times 2$), respectively.

B. equi has been renamed as *Theileria equi*. Infections are more refractory to therapy, and some cases may be cleared with imidocarb. Thus recommended doses of drugs must be enhanced to obtain elimination of carrier infections. However, marked increase of dose level and repeated injection often lead to undesirable acute side effects and occasionally to mortality. Obviously there are

different susceptibilities among *B. (T.) equi* strains to drugs. Antitheilerial compounds parvaquone and buparvaquone (Table 1) have also been shown to have some efficacy against parasitemia of initial *B. (T.) equi* infection indicating an action chiefly directed against schizontal stages. Halofuginone lactate can also be used to treat *cryptosporidiosis* of calves (EC approved indication) and was used experimentally to treat *sarcosporidiosis* of goats and sheep (cf. Table 1).

Theileriasis

Theileriosis. Tick Bites: Effects in Animals.

Theileriosis

Synonyms

Theileriasis

General Information

► *Theileria* species are tick-borne protozoan parasites which cause infections of ruminants characterized by successive developmental stages in leukocytes and erythrocytes. In contrast to other apicomplexan protozoans such as ► *Plasmodium* and ► *Babesia* which cause disease by destruction or sequestration of erythrocytes, pathology produced by ► *Theileria* is attributable mainly to the intraleukocyte stage. The severe, often fatal diseases in ruminants cause huge economic losses to the cattle industry, primarily in East and Southern Africa. In the horse, *Babesia equi* which has now been redescribed as *Theileria equi*, is also a major pathogen.

In cattle, the most important species in East and Southern Africa is *T. parva*. Two types are generally recognized: *T. parva parva* which causes East Coast Fever and *T. parva lawrencei* which

causes ► [corridor disease](#). *T. annulata* causes theileriosis in North Africa, the near Middle East, Southern Europe, and Central Asia (e.g., ► [Mediterranean Coast Fever](#)). *T. mutans* has a very wide distribution and is generally benign, except in some parts of East Africa where it is reported to cause severe disease. *T. lestoquardi* (*T. hirci*) and *T. ovis* are parasites of sheep in North Africa, Southern Europe, and Asia.

Pathology

When introduced into a non-endemic region, **East Coast Fever** normally kills 90 % or more of the susceptible cattle population. In endemic areas the severity of the disease is greatly reduced, particularly in calves which develop only subclinical infections when exposed to moderate tick challenge. Susceptible animals introduced into enzootic areas rarely survive the infection. The disease is characterized by high fever, lymphadenopathy, severe pulmonary oedema, and wasting. The fever follows a severe panleukopenia and remains high until recovery or death, which commonly occur after a course of 5–25 days. Oedema of the eyelids and lacrimation are often present. Dyspnoea and a soft moist cough usually occur in terminal stages, sometimes with a voluminous frothy nasal discharge. At necropsy, the most obvious finding is often a severe pulmonary oedema. Lymph nodes are enlarged, oedematous, and may contain haemorrhages. Multifocal lymphoid ► [hyperplasia](#) may be visible as white spots within the renal cortex. Infection with *T. parva lawrencei* induces clinical signs and pathological changes very similar to those of East Coast Fever. The differentiation between the two diseases is mainly based on epidemiological grounds: ► [Corridor Disease](#) is transmitted to cattle by ► [ticks](#) of the African buffalo and occurs only in areas within the distribution of *Syncoerus caffer*. The clinical signs of Tropical Theileriosis are very similar to those of East Coast Fever, except maybe that in the former disease ► [anaemia](#) becomes more severe and icterus may be present. Leukocytopaenia does not usually develop in tropical theileriosis. However, the geographical ranges of *T. annulata* and

T. parva parva do not overlap except, perhaps, in some parts of East Africa. The pathogenesis of *T. mutans* is entirely associated with the proliferation of the intraerythrocytic ► **piroplasms**. The disease is normally mild in character, but cases of anaemia, icterus, and haemoglobinuria, have been reported from East Africa. *T. lestoquardi* (*T. hirci*) is pathogenic in sheep and goats, clinical signs resemble those of East Coast Fever in cattle.

The horse parasite *T. equi* has recently been redescribed. It is highly pathogenic and induces the following clinical signs: high fever, listlessness, lacrimation, oedema of the eyelids, severe anaemia, ► **haemoglobinuria**, and icterus. Pathological findings include emaciation, anaemia, and icterus, hepatomegaly and splenomegaly, lymphadenopathy, oedema of the lungs, ascites, hydrothorax, and hydropericardium.

Immune Responses

In the following section we will focus on *T. parva*.

Development from ► **sporozoite** to ► **schizont** inside leukocytes induces activation and proliferation of the host cell. This process results in rapid clonal expansion of parasitized cells and thus allows the parasite to remain intracellularly. As a consequence, immunological control of established infections is largely T-cell mediated. Studies in vitro have demonstrated that *T. parva* can infect $\alpha\beta$ T cells (both $CD4^+$ and $CD8^+$), $\gamma\delta$ T cells, and B cells with similar frequencies. However, in vivo the vast majority of infected cells are $CD4^+$ and $CD8^+$ T cells and infection of unfractionated blood mononuclear cells usually gives rise to $\alpha\beta$ T-cell lines. Infected cells constantly express high levels of class I and II MHC molecules.

The reservoir host of *T. parva*, the African buffalo, does not develop disease despite the fact that its cells are equally susceptible to infection and transformation by the parasite in vitro. Since in contrast experimental infection of susceptible cattle results in an acute fatal disease in the majority of animals, most studies on the immunity to *Theileria* spp. have been performed in an

“infection and treatment model.” In this model, the treatment with a slow-release formulation of oxytetracycline at the time of infection allows animals to recover from infection.

B Cells and Antibodies

Studies with immune sera and mAbs have failed to demonstrate expression of *Theileria* antigens on the surface of parasitized lymphoblasts. Because of the apparent absence of such antigens on the cell surface and the intracellular localization throughout this stage of development it is not surprising that passive transfer of immune serum to susceptible animals failed to give any protection. However, sporozoite-specific antibodies capable of neutralizing infectivity in vitro have been detected in cattle in endemic areas. The major specificity recognized by these sera appeared to be a 67 kDa protein (p67) which has been cloned and used as recombinant immunogen in vaccination studies. Although all immunized animals generated strong antibody responses with similar titres, isotype patterns, avidity, and epitope specificity, only 70 % of the cattle were protected against challenge infections. Thus it is not clear yet whether protection induced by p67 immunization relates to antibody function.

T Cells

Immunization of cattle by infection and treatment elicits a strong MHC-I restricted specific response of $CD8^+$ cytotoxic T cells (CTL), whereas parasite-specific CTL are not detected at any stage of the primary infection with *T. parva*. In immune animals the frequency of detectable CTL precursors is relatively constant (1:2000–1:12000) at 5–6 weeks p.i. but reaches levels as high as 1:30 in efferent lymph to 1:600 in PBMC following challenge with sporozoites. The strain specificity of CTL responses varied between animals immunized with the same parasites but only a restricted, immunodominant subset of epitopes appeared to be recognized. Furthermore, in many MHC-heterozygous animals a single class I molecule determined the epitopes that were recognized by CTL. The molecular and cellular events leading to

immunodominance are not understood but are likely to involve variation in the concentrations of antigenic peptides bound to the presenting MHC molecules and the composition of the T-cell receptor repertoire. Cell transfer experiments utilizing identical twin calves produced by embryo splitting have shown, that CD8⁺ T cells mediate protection. Whether they exert their effect solely by killing parasitized cells or by cytokine-mediated mechanisms has not been investigated in detail. There is some evidence that TNF as well as other cytokines may inhibit early Theileria development inside lymphocytes, but none of the cytokines tested so far inhibited established infections. In addition, a wide range of cytokines, such as IL-2 and IL-10, appears to be expressed by *T. parva*-infected cells themselves.

Although the majority of studies have focused on the role of CD8⁺ T cells, there is no doubt that parasite-specific CD4⁺ T cells are generated following immunization with *T. parva*. Some cloned CD4⁺ T cells have been shown to produce IFN- γ indicating that they are Th1-like. However, the functional role of CD4⁺ T cells in *T. parva* infection, for example, as helper cells for the establishment of a CD8⁺ T-cell response or as anti-parasitic effector cells, has not been analyzed.

During primary infection of cattle with *T. parva* the lymph node draining the site of infection undergoes a dramatic threefold to fourfold increase in size 7–9 days after infection. Proliferation of mainly CD8⁺ T cells is induced which contain a large subset of CD2⁺ T cells. The latter cells may be derived from a rare pre-existing population and are polyclonal in origin as shown by analysis of their TCR repertoire. Analyses of the stimulatory requirements and function of these CD2⁺CD8⁺ T cells have been hampered by the inability to culture them in vitro. Since only a minor part of the lymphoblastic cells in the lymph nodes is parasitized, the question has been raised, whether or not the T-cell response in naive animals contributes to the pathogenesis of the disease by potentiating the growth of parasitized cells. Since parasitized cell lines express cytokine receptors such as CD25 (IL-2 receptor, p55) and their growth could be enhanced by

cytokines like IL-2, IL-1, and IL-10 in vitro, it is likely that the induction of an early cytokine expression in the infected host could help parasitized cells to multiply. Transfer studies with lymphocytes infected in vitro with *T. parva* sporozoites clearly demonstrated that the cell type infected influences the pathogenicity of the parasite. While infected CD4⁺ or CD8⁺ T cells induced severe, potentially lethal infections, infected B cells produced only mild self-limiting disease. The factors that determine the difference in the pathogenic potential of parasitized B and T cells have not been identified so far.

Vaccination

A number of attempts to produce commercially available products have not yet been successful. *T. annulata* can be grown in culture using lymphocytes or fibroblasts as host cells. If this cultivation is done over a longer period of time, the virulence of the parasite is attenuated. In Israel, vaccination of cattle against *T. annulata* was introduced using attenuated cultured schizonts which are distributed in frozen form. The use was generalized in wide scale in North Africa and Asia and provides very effective control.

The search for attenuated vaccines against *T. parva* has not yet reached the same stage. However, in spite of the high costs, vaccine using live parasites has been used. The strategy of such a vaccine is based on the injection of live schizonts followed by treatment of the animal with tetracycline. More recently an attenuated *T. parva* isolate Boleni, has been used with success without concurrent tetracycline therapy. The main hindrance is that suitable infective parasite materials, i.e., sporozoites, can only be obtained from the salivary glands of the ticks. Sporozoites have been successfully used to obtain protection in cattle by injecting them frequently together with tetracycline. In vaccination trials, cattle immunized against *T. parva* with this technique developed immunity against the homologous sporozoites as well as those of *T. parva lawrencei* and a number of other *T. parva* strains, indicating that there is a

common protective antigenic determinant on the sporozoites used for vaccination. Doherty and Nussenzweig mentioned in 1985 that a number of monoclonal antibodies do not distinguish between sporozoites of the various *T. parva* strains.

A 67 kDa protein on the surface of the sporozoite of *T. parva* was identified as target antigen. Corresponding recombinant molecules have been used in vaccination experiments but producing partial protection. An equivalent recombinant protein SPAG-1 from *T. annulata* was also used, also producing partial protection. Intensive efforts have been focused on the identification of schizont-specific components for incorporation in a second-generation multi-component product, but these efforts remain so far inconclusive. Attenuated vaccines lines of *T. annulata* and *T. parva* are at the present time the only practical solutions for theileriosis control. Thus the molecular biology studies on the mechanisms of parasite virulence remain a priority in the hope of achieving a rational attenuated parasite line for vaccination.

Oxyurid nematode in the intestine of cockroaches and beetles.

Thelazia

Classification

Genus of ► [Nematodes](#).

General Information

The genus *Thelazia* comprises nematode worms, commonly named ► [eyeworms](#), which infect mostly the eyes and associated tissues of many domestic and wild animals (Table 1). However, they are also found in the nose and pharynx. Transmission occurs via non-biting dipterans

Thelazia, Table 1 Some *Thelazia* species, hosts, vectors, and their geographic distribution

Species	Hosts parasitized	Vectors	Geographic distribution
<i>Thelazia californiensis</i>	Canids, felids, domestic and wild ruminants, humans	<i>Fannia benjamini</i> , <i>F. canicularis</i>	North America
<i>T. gulosa</i>	Domestic and wild ruminants	<i>Musca amica</i> , <i>M. autumnalis</i> , <i>M. domestica</i>	Europe, Asia, North America, Australia
<i>T. lacrymalis</i>	Equids, domestic and wild ruminants	<i>M. autumnalis</i> , <i>M. osiris</i>	Europe, North and South America
<i>T. leesei</i>	Camels	<i>M. lucidula</i>	Ex-USSR, India
<i>T. rhodesi</i>	Domestic and wild ruminants, horses	<i>M. autumnalis</i> , <i>M. domestica</i> , <i>M. larvipara</i>	Europe, Asia, Africa, North and South America
<i>T. skrjabini</i>	Domestic and wild ruminants	<i>M. amica</i> , <i>M. autumnalis</i> , <i>M. hervei</i> , <i>M. osiris</i>	Europe, Asia, North America, Australia

Thelazia, Fig. 1 SEM of adult female *Thelazia rhodesi* worm (mouth); bar = 0.1 mm (Courtesy Dr. Naem, Iran)

Thelazia, Fig. 2 SEM of adult male *Thelazia rhodesi* worm (mouth); bar = 0.2 mm

Thelazia, Fig. 3 SEM of cuticular sensory papillae of *Thelazia skrjabini*

Thelazia, Fig. 4 Coiled posterior pole of a *Thelazia gulosa* male, showing the 2 different spicula; bar = 0.1 mm (Courtesy of Dr. S. Naem, Urmia, Iran)

that lick ocular secretions at the conjunctiva of animals. However, **human cases** (e.g., *T. californiensis* of dogs, cats, deer in North America) are also common in poor socio-economic regions in many Asian countries (e.g., *T. callipaeda* from rats, dogs, rabbits).

Morphology

The adult worms grow up to 18 mm as females of *T. lacrimalis* (males 11 mm) (in horses, cattle, dogs in Europe, South Africa, South America) and of *T. rhodesii* (in cattle, horses, worldwide).

The females release microfilariae (L_1), which are taken up by feeding flies. Within the vector's intestine the development proceeds, until the infectious L_3 -stage is reached (within 9–12 days). During next feeding the L_3 emerge from the labellum of infected flies, start feeding on the lacrymal secretions of the new hosts and develop into the adult stage within 3–4 weeks. The adults live for 2–3 months. Morphological characteristics are the roughly striped cuticle, the absence of lips, a short oesophagus, and the differently sized spicula of males (Figs. 1, 2, 3, and 4, page 1374–1375). Some species are viviparous (see above), others excrete larva-containing eggs.

Symptoms of Disease

Inflammation of eyes, keratitis, blindness.

Therapy

Nematocidal Drugs, mechanical extracting of the worm from the conjunctival sac.

Thelazia callipaeda

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This nematode, which is also called oriental eye-worm, was originally described from animals and humans in Eastern countries (former Soviet Union, India, Thailand, Indonesia, Myanmar, Korea, China, and Japan). However, in recent years it has been increasingly reported in both animals and humans from Western countries ranging from Spain, Portugal, Italy, France, Germany, and Switzerland to many countries of the Balkans and Greece. It is one of at least 16 species belonging to the genus ► *Thelazia* leading to conjunctivitis, keratitis, epiphora, etc. Transmission apparently occurs by fruit flies (e.g., *Phortica variegata*).

Thelazia Species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

1. **Name:** Greek: *thelys* = female nipple. English: Eye worm.
2. **Geographic distributions/epidemiology:** Worldwide, in mammals (cattle, horses, humans, carnivores) and birds; often prevalence rates of up to 50 %.
3. **Morphology/life cycle:**
 - (a) **Ruminants:** The species *T. gulosa*, *T. rhodesi*, and *T. skrjabini* appear whitish yellowish; the females reach a length of 19 mm, the males 8–12 mm. The spicula of the males is mostly rather large. The vulva of the females is situated close to the anterior end. Some species parasitize in the conjunctival sack of the eyes, others inside the lacrimal channels. The females give birth to microfilariae, which are ingested by flies of the genus *Musca* when licking lacrimal fluids. After 9–12 days inside the intestine, the infectious larva is formed and may be transmitted during the next touchdown at an eye of a host. There they reach maturity within 3–4 weeks.
 - (b) **Equids:** *T. lacrymalis* (♀ = 18 mm; ♂ = 11 mm) parasitizes inside the conjunctival sack. Eggs are attached at the conjunctiva from where they are ingested by *Musca autumnalis* and related flies when licking lacrimal fluids. The infectious larva is formed within 2 weeks. This larva leaves the mouthparts during the next host visit and thus enters the eye of horses, etc.
 - (c) **Birds:** Mostly specimens of the genus *Oxyuris* are found in the conjunctival sack of the bird's eye.

- (d) **Carnivores:** Among carnivores, the Asian species *T.callipaeda* is actually spreading.
- (e) **Humans: Attention:** All above-cited *Thelazia* species have a considerable zoonotic potential, since transmission occurs mechanically.
4. **Symptoms of disease:** In cases of a few larvae, the infection remains inapparent; however, high-graded infections lead to increased production of lacrimal fluids, which attract flies. Furthermore, the following symptoms may occur: conjunctivitis, iritis, iridocyclitis, and edemas. Degenerating microfilariae induce clouding of the cornea, closing of the eyelids, and increased sensitivity to light.
 5. **Diagnosis:** Microscopical inspection and extirpation of larvae or adults by the help of eye rinsing.
 6. **Infection:** Contact of infected flies to eyes.
 7. **Prophylaxis:** Use fly gazes before windows in houses and achieve fly control in stables.
 8. **Incubation period:** 1–2 weeks in cattle, 2–3 days in horses and humans.
 9. **Prepatent period:** 3–4 weeks in cattle, 11 weeks in horses.
 10. **Patency:** About 12–15 months in cattle, 2–3 months in horses.
 11. **Therapy:** Eye rinsing and mechanical removal of worms. Levamisole (1–3 days always 5 mg/kg body weight subcutaneously or orally, respectively; 2 ml injected directly into the conjunctival sack). Furthermore, ivermectin (0.5 mg/kg body weight as spot-on) or doramectin (0.2 mg/kg body weight subcutaneously) have been shown highly effective.

T-Helper Cells (Th)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes a group of T cells, which are characterized by the expression of the CD4 co-receptor and which are restricted to association with antigen/MHC class II complexes. These cells are important for the activation of macrophages,

B-cell responses, and regulation of immunity when they had been differentiated into one of several functionally different subsets (e.g., Th1, Th2, Th17, Treg, Tr1, etc.):

- Th1: Subset of CD4 helper cells which is involved with IFN- γ and TNF- α expression and resistance to intracellular pathogens

Theobaldia

Former genus name for ► *Culiseta*-mosquitoes.

Therapeutic Targets (TT)

A drug of choice is best, if it has a fixed target, which steers such an important mechanism in the physiology of a parasite, that it cannot survive or reproduce without it. For example, in *Plasmodium falciparum* there are several TT dependent on the attacked system:

1. **Targets in apicoplast:** fatty acid synthesis, isoprenoid synthesis; **new drugs:** triclosan, fosidomycin.
2. **Targets in cytosol:** glycolysis, pyrimidine synthesis, folate pathways; **existing drugs:** antifolates, atovaquone.
3. **Targets in food vacuole:** heme detoxification; **drugs:** chloroquine, aminoquinolines; **new targets:** falcipains, plasmepsins; **drugs:** protease inhibitors.
4. **Targets in mitochondrion:** respiratory chain; **drug:** atovaquone.

Thermal Response Curve

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This curve shows the phenotypic response of an organism (including parasites) over a range of temperatures given in a peculiar biotope. The outcome can influence a process (e.g., to steer enzyme activity), influence a trait (e.g., size), or influence general fitness. The curve is characterized by its cold and warm extremes (CT_{min} , CT_{max}) and the peak (T_{opt}). Each curve only represents the response of a single genotype over a range of environments.

Thermy

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *thermos* = warm, hot; *heteros* = different, other; *endos* = inner; *ektos* = outside; *endon* = inside.

This term describes the physiological body situation of animals (including parasites, which have stages inside and outside of a body). There are different types:

- **Ectothermal animals:** These animals depend on the external temperatures to maintain their body temperature (e.g., mosquitoes, ticks, worms, reptiles).
- **Endothermal animals:** These animals generate their body temperature independent of their environment (e.g., birds, mammals).
- **Heterothermal animals:** These animals can switch between an ectothermic or endothermic stage within their life cycle. This type is typically found in animals that hibernate and thus response to the conditions in their surroundings. In case of intestinal stages or worm adaptation to high temperatures is required, while their outdoor stages depend on the temperatures on the ground (e.g., hookworms or strongylid nematodes and their external larvae).
- **Homeothermal animals:** Animals of this group are able to maintain a stable body temperature regardless of external environmental conditions (e.g., mammals). Parasites are not known in this group except for, e.g., blood-licking ► [vampire bats](#).

Genus of snails that act as intermediate hosts in ► [Paragonimus](#) transmission.

Thick Droplet Method

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

It is a method developed to detect low-grade parasitemias in infections with ► [Plasmodium](#) species or *Babesia* species. See ► [Giemsa stain](#).

Thick-Walled Vesicle

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This organelle is situated anterior to the centrally located nucleus of merozoites and sporozoites of ► [Apicomplexa](#) (formerly called Sporozoa). In early electron microscopic studies, its covering membranes could not or only be badly dissolved, and thus, they were kept together as a thicker layer. Today, it is known that this organelle is covered by four different membranes. Since it is proven that it is formed by invasion of an already infected endosymbiont, it is called ► [Apicoplast](#), which is located at the apical pole of motile stages of ► [Apicomplexa](#).

Thigmotaxis

Movement after touching or instabilisation.

Thiolproteinases

Thiolproteinases are widely spread in the animal kingdom. In parasites at least 3 groups had been defined acting similarly like cathepsin L of humans:

- Cruzipain (syn. cruzain) is described in *Trypanosoma cruzi* and possesses a very long C-terminus consisting of 149 amino acids. It steers the metacyclogenesis (i.e., the change from amastigote stages into ► [trypomastigotes](#) and inverse).
- Falcipain (syn. trophozoite cysteine proteinase = TCP) is found in *Plasmodium falciparum* and plays its role during the separation of the hem – component from the globin during digestion within the intraerythrocytic food ► [vacuoles](#).
- Sm 219. This thiolproteinase was found in ► [tachyzoites](#) and ► [bradyzoites](#) of ► [Toxoplasma gondii](#) and ► [Sarcocystis](#) spp. In the first case it is found in the ► [rhoptries](#), while in *Sarcocystis* (where 219 aminoacids are noted) it is localized in the ► [dense bodies](#) and becomes thus excreted into the rising ► [parasitophorous vacuole](#)

Thiols

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Low-molecular-weight thiol compounds and their associated enzymatic recycling systems are responsible for the protection of cells against oxidative stress and the maintenance of an optimal intracellular redox state. In most eukaryotes, including helminths, glutathione (GSH, γ -glutamyl- L-cysteinylglycine) in conjunction with various enzymes, such as GSH reductase, GSH peroxidase, catalase, and superoxide dismutase, fulfills these important functions. Although the majority of parasites appears capable of GSH biosynthesis, many of them, in particular protozoans, lack an effective enzymatic equipment to protect themselves against reactive oxygen metabolites. Catalase and GSH peroxidase are often missing, but with the exception of anaerobic protozoa most parasites contain superoxide dismutase for removal of superoxide and use specialized enzymatic systems in their thiol redox and detoxification mechanisms (Fig. 1).

Thiols, Fig. 1 Some basic mechanisms of detoxification and the associated role of thiol compounds in protozoa and helminths. 1, Superoxide dismutase; 2, catalase; 3, thiol-dependent peroxidases; 4, thiol reductases. GSH and GSSG, reduced and oxidized forms of glutathione; TSH and TSST, reduced and oxidized forms of trypanothione

Plasmodium falciparum uses a rather complex GSH- and thioredoxin (Trx)-dependent enzymatic system, including GSH reductase, Trx reductase, a whole set of peroxiredoxins, and other redox enzymes to maintain its intracellular redox balance. In common with various prokaryotes, anaerobic protozoa lack GSH and its recycling enzymes, together with other defending antioxidants, such as catalase and peroxidases (Fig. 1). Instead, these parasites use cysteine as the major GSH substitute along with a disulfide reductase as the thiol recycling enzyme. Like in the Trx reductase/Trx or peroxiredoxin/Trx systems of *P. falciparum*, Trx functions as an intermediate electron carrier between the disulfide reducing enzyme and the thiol. Thioredoxins are ubiquitous, low-molecular-mass polypeptides that are reoxidized by NADPH-dependent thioredoxin reductase. An exceptional thiol metabolism is observed in kinetoplastids. These protozoans lack GSH reductase and Trx reductase but contain a trypanothione/trypanothione reductase-dependent system instead. Trypanothione (N¹,N⁸-bis (glutathionyl)spermidine) is a novel thiol, in which GSH is conjugated with spermidine to form a cyclic peptide that is used in trypanosomatids to regulate the intracellular redox environment and detoxify free radicals and other toxic compounds. The protective thiol is synthesized from spermidine and glutathione by the consecutive action of two distinct enzymes, glutathionylspermidine synthase and trypanothione synthase. Trypanothione is maintained in its reduced form by the action of trypanothione reductase. Other recently identified components of the trypanothione-dependent metabolism are tryparedoxin and tryparedoxin peroxidase. These proteins are, together with trypanothione and trypanothione reductase, constituents of a complex peroxidase system that kinetoplastids have evolved to detoxify hydroperoxides.

Thominx Species

Genus of the nematode family Capillariidae (hairworms) of birds.

Thorax

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes the breast in the case of vertebrates. In ► [insects](#) the thorax comprises three segments following the head (prothorax, mesothorax, metathorax).

Thorny-Headed Worm

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Trivial name for ► [Macracanthorhynchus hirudinaceus](#) (► [Acanthocephala](#)).

Threadworm Disease

Synonyms

Strongyloides stercoralis (Strongyloides).

Thrombocytopenia

Reduction of thrombocytes in infections with *Babesia* spp. or in malaria.

Thrombospondin-Related Adhesion Protein (TRAP)

One of the circumsporozoite proteins (CSP), that are involved in the movements of *Plasmodium* sporozoites.

Thynascaris

Synonyms

Genus name for *Contracaecum* spp. parasitizing fish (Ascaroidea-group).

Thyrsocnema incisilobata

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Fly species, the larvae of which may induce a so-called urogenital myiasis.

Further Reading

Thysaniezia

Name

Greek: thysanos = ruptured ends.

General Information

Genus of anoplocephalid cestodes. *T. giardi* is found in cattle in Europe, Asia, Africa, and America, reaches a length of about 2 m, and its terminal proglottids are characterized by a uterus with several paruterine organs containing 25 µm eggs (Fig. 1).

Thysanosoma

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

A genus of cyclophyllidean tapeworms belonging to the family Anoplocephalidae. The scolex possesses four suckers; each proglottid contains two sets of both sexual systems (♀♂). The genital poria are situated at the side of the proglottids. Ovaries are arranged in rosette-like structures; uteri are united to a winding tube. Eggs are situated in numerous egg capsules possessing a pear-like apparatus. Mites are intermediate hosts containing a cysticercoid. Adult worms parasitize in ductules of the gall bladder of ruminants.

Thysaniezia, Fig. 1 DR of a proglottis of *Thysaniezia*. *EL* longitudinal excretory channel, *EQ* cross excretory channel, *GP* genital porus, *HO* testis, *OV* ovary, *PR* proglottis, *UPA* anlagen of the paruterine organs, *VI* vitellarium

Thysanosoma actinoides

Tapeworm of ruminants, which is found in the small intestine and in the ductus pancreaticus. This species has two sets of genitalia in each proglottids.

Thysanotaenia congolensis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This species belongs to the cyclophyllidean, anoplocephalan cestodes infesting the intestine of rats (*Rattus rattus*, *Thryonomys gregorianus*). The number of egg capsules reach 120–150 per proglottid, each containing 6–12 eggs with a diameter of about 25 µm.

Tiabendazol

Other spelling for thiabendazole, Nematocidal Drugs.

Tiacc-arana

Leishmaniasis due to *L. peruviana*. Other common names are uta, llaga.

Tibia

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Portion of the leg in vertebrates and in insects (the coxa, trochanter, femur, tibia, tarsus)

Tick Antigens

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Tick vaccines became commercially available in the early 1990s for the control of cattle tick infestations (especially in Australia). Most of them are derived from the midgut of the one-host tick *Boophilus microplus* (BM86). Several BM86 orthologs and homologs have been identified in *Boophilus annulatus* (BA86) and *Hyalomma anatolicum anatolicum* (HAA86) and in *B. microplus* (BM95). Several salivary gland antigens have also been described, e.g.:

- **64TRP** is a tick protein of *Rhipicephalus appendiculatus*.
- **Salp25D** is expressed by *Ixodes scapularis*.
- **THRF** (tick histamine release) is also produced by *Ixodes scapularis* and apparently important in *Borrelia* transmission.
- **TSLPI** (tick salivary lectin pathway inhibitor) is produced by *Ixodes scapularis*.

Tick Bites: Effects in Animals

General Information

► **Ticks** play a major role in the human economy by causing significant losses in animal production through their own direct effects, as well as by transmitting diseases to domestic stock. In temperate and tropical countries, ticks surpass all other arthropods in the number and variety of

diseases they transmit to animals. Disease agents transmitted to animals by ticks include viruses, rickettsiae, bacteria, fungi, and protozoans. In a few cases, helminths have also been found in ticks. A summary of the most important pathogens transmitted by ticks to animals is shown in Table 1. Direct effects of ticks are manifested as mechanical injury, anemia, paralysis, and toxicosis. These may be extended by secondary infections with bacteria, fungi, or myiasis.

Tick Bites: Effects in Animals, Table 1 Tick-borne bacteria, rickettsiae, and protozoans in domestic animals

Tick vector	Pathogen	Host	Disease
<i>Argas reflexus</i>	<i>Borrelia anserina</i>	Poultry	Avian spirochaetosis
	<i>Aegyptianella pullorum</i>	Poultry

	<i>Haemobartonella canis</i>	Dogs	Bartonellosis

Lesions

In most cases the bite of a tick is not felt at first, but it can be painful in ► *Amblyomma* spp., which have very long mouthparts. Even if ticks are removed by grooming, persistent lesions can remain.

Mechanical injury to the host is initiated by the penetration of the mouthparts into the skin, during which the ► *chelicerae* serve to cut into the epidermis, causing some damage to capillaries and tissues. The recurved denticles of the ► *hypostome* serve to anchor the tick within the lesion. The depth to which inserted mouthparts enter the host's skin depends on the morphology and feeding habits of the tick species. Those with long mouthparts, such as members of the genera *Amblyomma* and ► *Hyalomma*, penetrate much deeper than ticks with short mouthparts, such as members of the genera ► *Boophilus*, *Dermacentor*, ► *Haemaphysalis*, and ► *Rhipicephalus*, which are superficial feeders. Female *A. americanum* ticks insert their mouthparts well into the lower reticular area of the dermis to the layer of adipose tissue. *Hyalomma asiaticum* penetrate to a similar depth in sheep.

The extent of tissue damage caused by tick feeding is not always clearly differentiated from host reactive tissue damage. The involvement of host reactions leading to tissue damage may be dependent upon recruitment and degranulation of mast cells, resulting in the release of heparin and histamine (or 5-hydroxytryptamine in bovines) from the granules, leading to inflammatory responses characterized by dermal cell infiltrates which form the lesion. The type of cell which infiltrates is dependent upon the tick/host systemy involved and can be predominantly neutrophil or mononuclear. The cell populations can change after multiple infestations. At the feeding site of *Hyalomma a. anatolicum* on rabbits, the extent of collagen destruction is parallel to the degree of neutrophil infiltration. Mated females *A. americanum* caused a more substantial inflammatory response than unmated females, which produced, on average, smaller cavities and lesions over the same

duration of attachment. Lesions from unmated females were the same size after 24 h as those from mated females after 48 h.

In fast-feeding argasid ticks, the leukocyte response is less marked than in the slow-feeding ixodid species. After primary feeding by *Ornithodoros parkeri* and *O. tartakovskyi*, basophils were found to accumulate after as little as 24 h in guinea pig skin. There was also a marked blood basophilic response, with weak ► *eosinophilia*.

The extent of local injuries can be influenced by the tick species and the site. There is a higher frequency of severe udder damage in cattle infested by *Amblyomma hebraeum* than in those infested by *A. variegatum*. Larvae and nymphs of *Otobius megnini*, the ► *spinose ear tick*, cause marked irritation in the ear canal, with secondary bacterial infections extending inward, sometimes resulting in serious complications.

Theoretical estimates of blood loss and ensuing damage due to ticks do not always apply to the field situation. In many cases the severity of effects is likely to be enhanced by toxic salivary excretions. Acute and even fatal anemia can occur in heavy infestations. *Argas persicus* can completely exsanguinate chickens, particularly young ones, within short periods.

Paralysis

► *Paralysis* caused by ticks is reversible when the causative ticks are removed, but it is sometimes difficult to clearly separate paralysis from toxicosis. Paralysis is usually associated more with female ticks and can be produced by a single tick. In Australia, paralysis is produced by *Ixodes holocyclus*, particularly in dogs, but sometimes also in other animals. In South Africa, Karoo tick paralysis is caused by *I. rubicundus*, mainly in sheep, as well as in other domestic stock. Also in South Africa, *Rhipicephalus evertsi evertsi* and *R. e. mimeticus* cause spring lamb paralysis while *Argas* ticks in the subgenus *Persicargas* cause paralysis in poultry. Other important paralysis-producing

species are *Dermacentor andersoni*, the Rock Mountain wood tick, which affects sheep and cattle, and *D. variabilis*, the American dog tick, which paralyzes dogs. A number of other species in several genera have also been incriminated. The distribution of paralysis due to a certain species of tick does not necessarily coincide with the total area of distribution of the species, and pathogenicity may also change within this area.

A paralysis-inducing toxin has been isolated in *I. holocyclus* and used as an immunizing agent. *Rhipicephalus evertsi* females are only able to produce toxin while they are within a specific weight range, which is of short duration when they are mated but prolonged in the absence of mating; thus there is increased risk of paralysis when females feed in the absence of males. This explains the higher frequency of some forms of paralysis in the field than in the laboratory, where in the past females have usually been provided with adequate numbers of males.

Toxicosis

Tick toxicosis is also associated with tick bite. A well-known African form is ► [sweating sickness](#), a disease of cattle, with profuse serum exudation onto the skin. It is caused by the bite of *Hyalomma truncatum*, a species of tick common throughout sub-sahelian Africa. Reactions to argasid ticks are more frequently caused by juvenile instars. *Ornithodoros savignyi* toxicosis can cause losses among cattle and *O. lahorensis* among sheep. The toxic component of oral secretions of *O. savignyi* was found to have a molecular weight of 15 kDa.

A variety of different pathogens can use lesions caused by ticks to infect animals. The bite of *Ixodes ricinus* is associated with tick pyemia, a disease of 2–6-week-old lambs in the UK caused by *Staphylococcus aureus*. A similar, usually fatal condition, caused by the same bacteria, has been found in rabbits infested with *R. appendiculatus*. It is thought to be related to immunosuppressive components of tick saliva.

Clinical Relevance

Clinical signs due to ticks are found in birds, reptiles, and mammals. There are reports of large tick burdens on some wild animals but the effects of ticks on individual animals are best known from domestic stock. Threshold values for production loss in domestic animals, i.e., changes in average daily weight gains, differ depending on tick species and hosts. For instance, weight gain was shown to be affected by 15 *Amblyomma americanum* females per calf, but far larger numbers of ticks are considered acceptable under other challenge situations.

Nevertheless, systematic tick control nearly always results in improved weight gain and yield in domestic stock. On the other hand, it has also been shown that under extensive husbandry conditions in dry African rangelands, cattle may make better weight gains in the absence of acaricide treatment, despite tick challenge.

Enormous tick challenge can be encountered in some parts of the world. The classic report of heavy infestation was by Theiler, who in 3 days removed half the *Boophilus decoloratus* ticks from a horse which had died of acute anemia and found them to weigh about 7 kg. In addition to blood loss and anemia, host animals are also affected by tick salivary excretion into the host, which may amount to at least the equivalent in weight of the engorged ticks. However, it must be accepted that most reports of massive harmful infestations with ticks involve either naive animals which have had no opportunity to acquire resistance, notoriously tick-susceptible species/breeds, e.g., Friesian (Holstein) cattle, or animals stressed by other causes.

Transmitted Pathogens

Many tick-borne diseases (Table 1) are characterized by a high degree of endemic stability, i.e., in areas with well-established populations of host animals, disease is experienced by most individuals, without more than passing clinical signs, and there is a high degree of immunity or premunity. Stability can be disturbed by the introduction of

susceptible, nonadapted hosts, after which serious outbreaks can occur in the new animals, inducing altered epidemiological conditions.

Virus diseases transmitted by ticks have been described from a large number of different hosts and are associated with a large number of different species of ticks (e.g., ► [African Swine Fever](#), ► [Nairobi Sheep Disease](#)). The presence of viruses in ticks in an area is not always associated with disease. In addition, ticks transmit protozoans (► [Babesia](#), ► [Theileria](#)), rickettsiae, and bacteria which cause severe diseases (► [Heartwater](#), ► [Streptothricosis](#)).

Tick Bites: Effects in Humans

General Information

► [Ticks](#) are a hazard to human health through direct effects as well as through the transmission of viral, rickettsial, bacterial, fungal, and protozoan diseases (► [Ticks/Important Species](#)). Their capacity as vectors for the transmission of human

diseases is surpassed only by that of ► [mosquitoes](#). A summary of some major diseases transmitted by ticks is shown in Table 1. Direct effects of tick activity include mechanical lesions, haemorrhages (Figs. 1 and 2), and paralysis.

Lesions

Some lesions are complicated by the mouthparts of ticks breaking off during manual detachment. This is rare in many tick species, but can occur in up to 50 % of *Ixodes* spp. female detachments. This can be followed by the formation of abscesses at the tick feeding site. The bite may not be known to the patient, particularly in cases where the tick is found on the scalp. This is a preferred site of *Rhipicephalus sanguineus*, a tick species which has spread rapidly during the recent past, attaching to children in temperate European countries. Some human cases of ear infestation with larval and nymphal spinose ear ticks, *Otobius megnini*, have also been reported.

Tick bites from ixodid ticks are sometimes biopsied because they give rise to a persistent ► [ulcer](#) with a necrotic base. In the center of the lesion, up to 2–3 mm into the dermis, one can sometimes find remnants of the chitinous mouthparts (► [Hypostome](#)) of a tick which was removed incompletely several months earlier. These irregular brownish fragments elicit an intense

Tick Bites: Effects in Humans, Table 1 Some important tick-borne viruses, bacteria, rickettsiae, and protozoans in humans

Tick	Pathogens	Diseases
<i>Ornithodoros</i> spp.	<i>Borrelia duttoni</i>	Relapsing fever
<i>Dermacentor</i> spp. and other ixodid species	<i>Rickettsia rickettsii</i>	Rocky Mountain spotted fever
	<i>Francisella tularensis</i>	Tularemia
<i>Ixodes dammini</i>	<i>Borrelia burgdorferi</i>	Lyme disease
	<i>Babesia microti</i>	Babesiosis
<i>Ixodes holocyclus</i>	<i>Rickettsia australis</i>	Queensland tick typhus
<i>Ixodes ricinus</i>	<i>Babesia microti</i>	Babesiosis
	<i>Babesia divergens</i>	Babesiosis
	<i>Borrelia burgdorferi</i>	Lyme disease
	Toga-/Flavi-virus	Meningoencephalitis
<i>Rhipicephalus sanguineus</i>	<i>Rickettsia conori</i>	Boutonneuse fever
Several ixodid species	<i>Rickettsia sibirica</i>	Siberian tick typhus
<i>Amblyomma</i> spp.	<i>Francisella tularensis</i>	Tularemia

hypersensitivity reaction and are embedded in necrotic connective tissue surrounded by fibrosis and an intense lymphohistiocytic reaction including eosinophils and basophils. The epithelium peripheral to the lesion undergoes acanthosis, hyperkeratosis, and focal parakeratosis.

The attachment of ticks is usually not felt, but may result in persistent irritation long after the tick has been removed. Larval ticks, also called ► [pepper ticks](#) or ► [seed ticks](#), cause a small lesion

which may lead to a relatively large inflammatory area remaining for several weeks. Large numbers of larvae are picked up when the offspring of a female tick crowd together on the vegetation. They will frequently attach on the ankles just above the socks and can cause intense and persistent itching.

Paralysis

Tick ► [paralysis](#) in man has been associated with *Dermacentor andersoni* and *D. variabilis* in North America, *Ixodes hexagonus* in Britain, and *I. holocyclus* in Australia, among others. Female ticks are usually involved. It is caused by a toxin and can lead to complete locomotory paralysis and death through respiratory paralysis.

Paralysis due to ticks is characterized by an acute ascending flaccid motor paralysis which can be fatal if the causative tick is not removed. In North America tick paralysis, the first symptoms usually appear 4–6 days after exposure. The cause of paralysis may not always be determined correctly, since the tick may be hidden by hair, which can lead to incorrect diagnosis. It is manifest at first as difficulty in walking, followed by inability to walk, limb numbness, and complete locomotory paralysis within 24 hours, difficulties in speech, respiratory paralysis, and death. Removal of the culprit tick results in rapid and complete recovery. In cases of extensive paralysis, recovery may be delayed for 1–6 weeks. Paralysis caused by *Ixodes holocyclus* in Australia does not usually peak until about 48 h after the tick involved has been removed. Accompanying symptoms are ► [vomiting](#) and acute illness.

Transmitted Pathogens

Ticks are more important as transmitters of disease (Table 1, Ticks/Important Species) than through their own direct effects. It is wise to regard all live ticks collected in the field for laboratory maintenance as potential sources of infection and they should always be handled with extreme caution. There are, unfortunately, too

many instances where neglect of this principle has resulted in loss of life or severe illness. The association of many tick species with migrating birds can allow a rapid movement of virus-infected ticks into new areas. It should be kept in mind that tick tissues or excretory products may contain infective agents which can be transmitted through contact or aspiration alone. It may be necessary to investigate ticks for the presence of unwanted virus infections before general handling can take place. Even apparently very closely related tick species may differ completely in their capacity to transmit pathogens. It can therefore be of great importance to identify tick species correctly.

Many tick-transmitted pathogens are likely to be carried by natural wild hosts (Reservoir), to which they are well adapted and in which they therefore cause no or only mild symptoms. At the same time, they can pose a serious threat to human beings or domestic stock, which may be severely affected and respond pathologically to infection. On the other hand, viruses have also been detected in ticks in areas where no disease is reported.

The ► [arboviruses](#) associated with ticks and human disease belong to the ► [Togaviridae](#), ► [Flaviviridae](#) (► [Flavivirus](#), group B), to the ► [Reoviridae](#), *Orbivirus*, and several ungrouped viruses.

Tick-transmitted rickettsiae usually do not persist for long in the peripheral circulation and the ticks themselves therefore serve as the main reservoir of disease. The best known is ► [Rocky Mountain spotted fever](#) caused by *Rickettsia rickettsii*, which is found from Canada to South America and is associated with various ixodid ticks (*D. andersoni* and *D. variabilis* in North America) which can transmit the pathogen transovarially to the next generation. ► [Tick typhus](#) is caused by other rickettsiae (e.g., *Rickettsia sibirica*). ► [Boutonneuse fever](#) is caused by *R. conori*, which is widespread in Africa, the mediterranean region, and parts of Southeast Asia. Queensland ► [tick typhus](#) is caused by *R. australis* and is found in coastal Queensland, where *Ixodes holocyclus* appears to be the main vector. The transmission of *R. prowazeki*, the agent of *epidemic typhus*, by ticks has not been confirmed, although at one time they were thought

to be vectors (► [Lice/Feeding Behavior and Transmission of Disease](#)).

Ticks are also known or suspected of harboring a number of bacterial infections of man. ► [Relapsing fever](#) is caused by spirochaetes (► [Borrelia](#) spp.) and is transmitted by ► [Ornithodoros](#) tick species. ► [Tularemia](#), caused by *Francisella tularensis*, is found in North America, reaching as far south as Venezuela, and is also found in parts of Asia and Europe. It is transmitted by *Dermacentor andersoni* (in the USA) and other tick species such as *Rhipicephalus sanguineus*. ► [Lyme disease](#) is caused by ► [Borrelia burgdorferi](#), a spirochaete-like bacterium transmitted by the ticks *Ixodes dammini*, *I. pacificus*, and *I. ricinus*.

Finally, ticks are vectors of many protozoan infections in man (e.g., Babesiosis, Man).

Tick Blood Digestion

Daniel Sojka

Institute of Parasitology, Biology Centre,
Academy of Sciences of the Czech Republic,
České Budějovice, The Czech Republic

Ticks are mite-related ectoparasites and vectors of serious diseases infecting humans and animals. Most of the ~850 worldwide distributed species are included in two major tick families Ixodidae (hard ticks) and Argasidae (soft ticks). Feeding and processing of host blood are essential physiological events since vertebrate blood presents an ultimate source of nutrients and energy for ticks. Tick gut tissue also presents the primary gate for pathogen entry. Mechanisms of avoiding or misusage of tick metabolic and immune pathways thus mean a basic prerequisite for the successful transmission of pathogens to their vertebrate hosts.

Physiology of feeding substantially differs between the two large tick families. In soft ticks, nymphs and the adults of both sexes take their blood meals rapidly, within hours, and then drop-off the host. Feeding and oviposition of soft ticks are cyclical processes, and feeding performance is not necessarily related to mating status because virgin females may conserve the nutrients in their gut tissues prior copulation. By contrast, hard ticks feed only once per life stage and engorged females die several days after oviposition. Hard tick female feeding lasts for days and consists of (i) slow feeding period taking 6–9 days followed by (ii) rapid engorgement 12–24 h prior detachment from the host. Rapid engorgement is conditioned by fertilization and accounts for about two-thirds of the total blood meal.

Processing of host blood components in tick midgut differs greatly from that in other hematophagous arthropods. In bloodsucking insects, protein digestion proceeds rapidly and takes place in the gut lumen. Digestive enzymes in tsetse flies, mosquitoes, and many other insects are mainly the trypsin-like serine proteases with a pH optimum in the alkaline range. In ticks, blood digestion is a much slower process that occurs in the acidic environment of gut intracellular vesicles. Tick gut is the major organ of their body and its middle part (midgut) is responsible for blood digestion. It comprises a ventriculus (stomach) and several pairs of highly branched ceca filling all regions of the female body (Fig. 1). The architecture of tick gut tissue includes gut lumen surrounded by a thin epithelial layer of histologically distinguishable cells and a thin outer layer of muscle fibers. Inner epithelium of the tube is covered by a peritrophic matrix analogous to the glycosaminoglycan peritrophic membrane of insects. Although a lack of uniformity persists in the nomenclature of tick midgut cells, it has been suggested that only one multifunctional cell type undergoes differentiation and endocytoses blood proteins for intracellular digestion during the slow feeding period.

Recently, substantial progress has been made in order to track the fate of hemoglobin within the gut tissue of *Ixodes ricinus* females. The whole process of hematophagy in hard ticks is

characterized with a chronological sequence of events demonstrated in Fig. 1. The first initial part is presented by the lysis of erythrocytes (hemolysis). Blood meal is then utilized by intestinal epithelium and protein degradation takes place in the endo/lysosomal apparatus of digestive gut cells (Sonenshine and Roe 2014). Hemolysis is not a simple event leaving red cell ghosts in the gut lumen but a complete enzymatic digestion of the red blood cell envelope that disappears totally. A cubulin-like serine protease tagged as H1SP was shown to be involved in the enzymatic hemolysis in *Haemaphysalis longicornis* (Miyoshi et al. 2004). Once released from erythrocytes, hemoglobin of some vertebrate hosts tends to form relatively large crystals in the tick gut lumen. A physiological rationale for this fascinating crystallization remains unclear, though food preservation or protection against a potential danger from hemoglobin surplus may be possibilities. Digestive gut cells take up blood proteins by heterophagy, which consists of at least two parallel endocytic mechanisms – as elegantly demonstrated by tracking fluorescent hemoglobin and albumin in a primary gut cell line of *Rhipicephalus (Boophilus) microplus* (Lara et al. 2005). Albumin seems to be taken up nonspecifically by fluid-phase endocytosis and is directed to a population of small acidic vesicles. Hemoglobin, however, seems to be recognized by specific cell-surface receptors, which target it to a population of large endosomal vesicles. Coated pits were also found in the midgut epithelium. The specific receptor-mediated endocytic (RME) pathway for hemoglobin most likely evolved as a detoxification mechanism against the potentially dangerous heme that is released upon hemoglobin digestion. Due to remarkable homologies, it is estimated that host hemoglobin recognition and trafficking in ticks comprises cellular molecular mechanisms analogous to clathrin-dependent receptor-mediated endocytosis of mammalian cells. Upon hemoglobin degradation in digestive cell vesicles, most of the heme is accumulated in the interior of specialized membrane-delimited organelles named hemosomes (Lara et al. 2003). Their development occurs in parallel to the detachment of digestive cells from the gut

Tick Blood Digestion,

Fig. 1 A schematic description of uptake and processing of host blood within the tick gut. *ER* endoplasmic reticulum, *p.m.* peritrophic matrix. For details, see text and references

epithelium during the slow feeding period and displays intracellular polarization.

A cascade or network involving cysteine and aspartic proteases has been proposed to catalyze hemoglobin degradation in many blood-feeding parasites. The network of clan CA (cathepsin B, L, and C), clan CD (asparaginyl endopeptidase – legumain), and aspartic (cathepsin D) proteases operating in the gut of the blood fluke *Schistosoma mansoni* is remarkably similar to that found in other trematodes, such as *Fasciola* and *Paragonimus*, and in the nematodes *Ascaris*, *Hemonchus*, and hookworms. Some other reports support the hypothesis that

protease gene network comprising cysteine and aspartic proteases evolved in early metazoans and remained widespread as a successful digestive proteolytic system up to vertebrates. Biochemical and reverse genetic screenings of semi-engorged (6th day of feeding) female gut of *Ixodes ricinus* demonstrated that this evolutionary old network of cysteine and aspartic peptidases maintains intracellular processing of host hemoglobin also in tick guts. Hemoglobinolysis is initiated by endopeptidases, cathepsin D (CatD) supported by cathepsin L (CatL) and legumain (AE), responsible for the primary events in the cleavage of hemoglobin. The endopeptidase activity of

cathepsin B (CatB) participates in the production of secondary, smaller fragments. The pool of peptide fragments released by these endopeptidases is degraded by the action of exopeptidases through the dipeptidase activities of CatB and cathepsin C (CatC). Mono-peptidases, including serine carboxypeptidase (SCP) and leucine aminopeptidase (LAP), might participate in the liberation of free amino acids (Sojka et al. 2013). Corresponding peptidase mRNAs IrAE1, IrCD1, IrCL1, IrCB1, and IrCC1 are expressed in blood-feeding lifestages. In females, they appear solely in guts with strong upregulation upon feeding in correlation with rapid increase of peptidase activities as displayed by dynamical qRT-PCR profiling and fluorescent substrate assays. This model is further supported by activity and reverse genetic reports from other hard tick species, before all from *R. microplus* and *H. longicornis*, and also from the soft tick *Ornithodoros moubata* (Sojka et al. 2013). Recombinantly expressed IrAE1, IrCD1, and IrCL1 are self-catalytically activated, display acidic pH optima of activities, and share unique substrate specificities with the authentic enzyme activities as determined by combinational synthetic peptidyl libraries and also by hemoglobinolytic cleavage patterns. IrCD1, IrAE1, and IrCL1 antibodies demonstrate feeding induced upregulation on Western blots of gut extracts and localization to the endo/lysosomes of gut cells. In comparison to GFP dsRNA injected controls, RNAi of IrCD1 and IrCL1 decreased gut cathepsin D activity by >80 % and cathepsin L by >95 %, respectively, confirming their nonredundant function in the hemoglobinolytic machinery. Furthermore, pilot experiments with rabbits indicate the potential of recombinant zymogens as anti-tick vaccines.

Conclusions

Ticks utilize host blood as their ultimate source of nutrients and energy. There are remarkable differences between feeding strategies of the major two groups of soft and hard ticks, and many questions remain to be answered about the differences in the molecular mechanisms of trafficking and

processing of host blood components. However, in contrast to insect blood-feeders utilizing extracellular trypsin-like serine proteases, digestion of host blood in ticks is maintained by the combination of cysteine and aspartic peptidases comprising AE/legumain, cathepsins B, C, D, and L, operating inside digestive gut cells at acidic pH. The mechanism is analogous to those found in phylogenetically distant nematodes and platyhelminthes. The specific endopeptidases of the *I. ricinus* digestive apparatus are currently tested as novel valid targets for tick control strategies.

Tick Control in Livestock

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Tick control must occur by repeating fixed programs (Table 1). One is proposed by Jonsson (2005) and others by Mondal et al. (2013).

Tick Control in Livestock, Table 1 Overview of tick control strategies

Strategy	Description
Absolute tick control	Zero tolerance approach to tick control. It is applied to historically tick-free areas adjoining infested areas or is applied after successfully eradicating ticks from the area
Absolute tick control (marginal or controlled area)	Mandatory control measures that are designed to eliminate ticks from defined areas that are usually marginally suited to the tick
Prophylactic treatment	Reduction of tick numbers to acceptable levels, reducing the risk of mortalities due to infestation or tick-borne diseases, and reducing losses in productivity
Threshold treatment	Ticks on a representative sample of cattle are counted, and when the average side counts of female ticks exceed a given threshold, treatment is applied
Opportunistic treatment	An extremely common approach to tick control in extensive production systems where the costs of mustering or gathering the animals are high. In these circumstances, cattle are often treated with acaricides when they are mustered for another purpose
Integrated tick control	A combination of a series of complimentary control measures to make the best use of each without placing too much reliance on any single component, including chemical and nonchemical control measures
Strategic tick control	A program that involves the application of acaricides from a predetermined commencement date and at specified intervals, regardless of the number of ticks present at the time of treatment. Basis of acaricide-driven eradication programs can also be used for long-term or sustainable control where eradication is not feasible
Selective acaricide application	Application of acaricides either to a proportion of all animals in a group or to a proportion of the bodies of all animals in a group

Tick Removal

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Ticks inject their bloodsucking mouthparts, which consist of a tubelike anterior protrusion (= hypostome), which contains a pair of skin-cutting knifelike so-called cheliceres into the skin. Ticks

Tick Removal, Fig. 1 Sucking tick at the human skin

are anchored to the skin by the fact that the injected tubelike protrusion possesses reverse hooks at its surface (Figs. 1 and 2). Since potential agents of diseases may be artificially injected during removal, if the body of the tick is pressed, it is necessary to fix the tick exclusively at the injected tube by the help of a most pointed tweezers and to extract the tick in this way without pressure on its body (Fig. 3). Covering the tick with alcohol, oil, or other substances must be

absolutely avoided, since this would introduce release of saliva and intestinal fluid into the biting site and thus potentially transfer agents of disease.

Tick Typhus

Tick typhus is caused by different rickettsiae. *Rickettsia sibirica* causes Siberian tick typhus which is transmitted transstadially and transovarially by ► [ticks](#) of the genera *Dermacentor* and ► [Haemaphysalis](#) as well as *Rhipicephalus sanguineus* and *Hyalomma asiaticum*. Ticks can serve as long-lived reservoirs of disease. Other arthropods may also play a role. Queensland tick typhus is caused by *Rickettsia australis* and is found in coastal Queensland, where *Ixodes holocyclus* appears to be the main vector.

Tick: Innate Immunity

Petr Kopáček
Institute of Parasitology, Biology Centre,
Academy of Sciences of the Czech Republic,
České Budějovice, The Czech Republic

Introduction

Ticks (Acari: Ixodida) are obligatory blood-feeding ectoparasites that suck blood and may harm their vertebrate hosts due to the severe blood loss. However, the main danger of ticks is their capability to transmit a wide variety of pathogens (e.g., viruses, bacteria, or protozoa) causing serious diseases to humans, domestic animals, or wild life. In human health, of great concern are, for instance, Lyme disease, tick-borne encephalitis, rickettsiosis, ehrlichiosis, or human granulocytic anaplasmosis. No less important are tick-transmitted zoonoses such as anaplasmosis, babesiosis, theileriosis, and African swine fever that cause substantial economic losses to the livestock production worldwide.

The tick vector competence is linked to the ability of transmitted pathogens to evade tick defense mechanisms acting in the tick gut, hemolymph, salivary glands, or ovaries (Hajdusek et al. 2013). Therefore, understanding the tick immune system and the molecular and cellular interplay that occurs between ticks and pathogens they transmit is of paramount importance.

The overall knowledge of tick immune system is rather scanty compared to invertebrate model animals such as the fruit fly, horseshoe crab,

freshwater crayfish, or tunicates (Iwanaga and Lee 2005). Also understanding of tick-parasite interactions lags far behind other blood-sucking vectors such as malaria mosquitoes or tsetse fly. This handicap has been progressively balanced during the last decade especially because of the release of the first tick *Ixodes scapularis* genome (<https://www.vectorbase.org/organisms/ixodes-scapularis>) and the feasibility of RNA interference allowing functional genomics studies in ticks. Commence of the post-genomic era in the research of tick-host-pathogen relationships may ultimately lead to the efficient control of ticks and tick-borne diseases.

Like other invertebrates, ticks lack adaptive immunity, and their defense against potential pathogens has to rely on the cellular immune responses such as phagocytosis and humoral factors involved in pathogen recognition and elimination (pattern recognition receptors, lectins, complement-like molecules, antimicrobial peptides, reactive oxygen species, etc.) (Kopacek et al. 2010, Fig. 1).

The primary site of tick-pathogen interaction and probably the decisive organ for the tick vector competence is the **tick midgut**. The imbibed blood is stored in the tick gut for weeks to months, depending on the developmental stage and tick species. Unlike in mosquitoes and other insect blood feeders, ticks digest blood intracellularly. This means that the microbes ingested by ticks are not in direct contact with digestive proteases secreted into the gut lumen and the highly nutritious broth of concentrated blood proteins, neutral pH, and long-term storage would present an ideal environment for microbial proliferation. Therefore, ticks have to possess potent defense mechanism which maintains the intestinal microflora at tolerable level. A significant role in the antibacterial activity against Gram-positive bacteria in the tick gut seemed to be played by **hemocidins** – the peptide fragments derived from the host hemoglobin. A similar antibacterial function of hemocidins was also reported in human placenta. To this end, two kind of endogenous antibacterial peptides typically active against Gram-positive bacteria have been reported to be secreted into the gut lumen of some tick

Tick: Innate Immunity, Fig. 1 An overview of the innate immunity in ticks. For details, see text and the references

species: (i) **defensins** – the cationic ~4 kDa peptides with a conserved pattern of six-paired cysteins, derived from ~8 kDa precursors termed as pre-prodefensins. Defensins act as molecular detergent which kill the bacteria by disrupting their outer membrane (ii) **c-type lysozymes** – basic ~14 kDa enzymes hydrolyzing 1,4 β -glycosidic bond between N-acetylmuramic acid and N-acetylglucosamine in cell wall peptidoglycans of Gram-positive bacteria. Almost nothing is known about defense against Gram-negative bacteria, fungi, and other microbes in the tick gut. Based on the paradigm of recent findings on epithelial immunity in the *Drosophila* gut and the role of redox balance in the vector competence of malaria mosquitoes, it is assumed that substantial part of the antimicrobial defense in the tick gut is executed by reactive oxygen species (ROS) and hydrogen peroxide. This hypothesis is

supported by the fact that tick midgut transcriptomes contain ROS-generating enzymes (NADPH oxidase 5, dual oxidase) and a myriad of antioxidant enzymes and radical scavengers (catalases, glutathione and thioredoxin peroxidases, glutathione S-transferases, selenoproteins, and others). The exact role of these enzymes in maintaining redox homeostasis in the tick gut and affecting the survival of intestinal microflora and persistence of transmitted pathogens remains to be thoroughly investigated.

On its route from the midgut to the salivary glands and host, a pathogen has to overcome the cellular and humoral immune reactions within the tick hemocoel. Ticks were reported to possess at least three types of hemocytes, namely, plasmatocytes and granulocytes I and II. Plasmatocytes and granulocytes I are capable of **phagocytosis** of foreign material and different

microbes. Interestingly, a process termed as “coiling” phagocytosis is involved in phagocytosis of *Borrelia* sp. spirochetes.

The cellular immune reactions in ticks seem to be associated with components of the tick **primordial complement system**. The process of self/nonself recognition is believed to involve the interaction of tick **lectins** (pattern recognition receptors, PRRs) with carbohydrates present on the surface of invading microbes (pathogen-associated molecular patterns, PAMPs). The lectins identified in tick hemolymph named as Dorin M or Ixoderins, in the soft ticks and hard ticks, respectively, are fibrinogen-related proteins (FREPs) similar to ficolins from mammalian complement system or tachylectin 5 from the horseshoe crab.

Ticks are unique among other invertebrates in that they possess representatives of all major classes of thioester-containing proteins (TEPs): (i) **α -macroglobulins**, the universal macromolecular protease inhibitors; (ii) **C3-components of complement system**; and (iii) **insect-type TEPs or MCRs** (macroglobulin complement-related proteins). It has been recently demonstrated by RNAi that phagocytosis of different microbes by the tick hemocytes depends on nonredundant involvement of various tick TEPs. Also genes coding for putative C3-convertases have been identified in the tick genome.

In contrast to insect and many other arthropods, ticks seem to lack the **prophenoloxidase activation cascade** ultimately leading to melanization and parasite killing. Also a defense mechanism based on **hemolymph coagulation** has not been yet unequivocally demonstrated in ticks, although some tick genes/proteins (e.g., limulus clotting factor C, transglutaminase) possibly involved in hemolymph clotting or wound healing have been identified.

Among effector molecules described to be active in the tick hemolymph, the reports on tick **defensins** are the most frequent. In addition to that, ticks also produce specific antimicrobial peptides that have not been found in other arthropods named as **microplusin**, **hebraein**, and **ixodidin**. Microplusin is a histidine- and cysteine-rich ~10 kDa peptide that exerts its bacteriostatic effect

by sequestering copper required for bacteria respiration.

Not much is known about innate immunity mechanisms in tick **salivary glands**, which are a rich source of pharmacologically active compounds modulating the host hemostasis, inflammation, immunity, and pain response. Next to defensin, microplusin, hebraein, and lysozyme genes identified in the tick salivary gland transcriptomes, a novel class of antimicrobial peptides named as **ixosins** have been described in this tissue. Recently, a family of **5.3 kDa proteins** was reported to play an important role in the tick interaction with the rickettsiae *Anaplasma phagocytophilum*.

Innate immunity in **ovaries** is important for pathogens capable of transovarian transmission. This is especially the case of the malaria-like apicomplexan parasite of the genus *Babesia*. Apart from antimicrobial peptides common to other tick tissues (defensins, microplusin), nothing is known about defense mechanisms in tick ovaries and eggs.

Regulation of innate immunity response to invading pathogen in ticks is still fairly unknown. Ticks possess a conserved Toll signaling pathway and at least some components of Imd and JAK/STAT signaling pathways leading to transcriptional regulation of immune genes via nuclear factor κ B. Exploring which specific tick immune response is controlled by which signaling pathway is a challenging task for future research in this field.

Conclusion

Despite its importance, the research of tick immunity is still in its infancy. The highest priority for future research of tick immune system and its interaction with transmitted pathogens should be focused on the following topics: (i) epithelial immunity and redox balance in tick gut; (ii) interaction between the pathogens and commensal microflora; (iii) the role of tick primordial complement system; (iv) regulation of tick immune response via Toll, Imd, and JAK/STAT signaling pathways; and (v) tick molecules

involved in the pathogen acquisition, persistence, and transmission.

Altogether, the solid pieces of knowledge achieved in these research areas can pave the way to the ultimate goal of efficient control of ticks and diseases they transmit.

Tick: Iron/Heme Metabolism

Ondřej Hajdušek

Institute of Parasitology, Biology Centre, Czech Academy of Sciences, České Budějovice, Czech Republic

Introduction

Ticks (Chelicerata, Arachnida) are blood-feeding parasites infecting their hosts with viral, bacterial, and protozoal pathogens. Lyme disease, tick-borne encephalitis, and babesiosis are the most common tick-transmitted human diseases. Tick feeding and infectious pathogens also greatly affect livestock production causing huge economic losses in many areas around the world (Jongejan and Uilenberg 2004; Hajdusek et al. 2013).

During the tick life cycle, larva, nymph, and adult stages occur. Importantly, every tick stage must feed once on a host blood to undergo consequent molting into the next stage (larvae and

nymphs) or to produce of huge amounts of eggs supporting rise of the next generation of larvae. Thus, blood is the only source of nutrients and other substituents important for the tick development. The water balance is coordinated by sophisticated action of salivary glands during (concentration of blood in the midgut bolus) and before feeding (hyperosmotic solution allowing water absorption from the air).

Unlike most of the other blood-feeding arthropods, tick digestion does not occur in the midgut lumen (insect secreted serine proteases, e.g., trypsin) but is located inside the midgut cells. Host hemoglobin, the most abundant protein in the blood (red blood cells), but also other proteins, are absorbed by the midgut cells and digested inside the lysosomal vacuoles by an orchestrated set of cysteine and aspartic proteases operating under low pH (Sojka et al. 2013). Heme and iron, released upon the digestion of host proteins, represent toxic substances (formation of free radicals damaging proteins, lipids, and DNA), which are detoxified and used by the ticks for their own purposes (Fig. 1). Genome sequence of *Ixodes scapularis* (deer tick) and molecular methods applicable in the tick research (e.g., RNA interference) allowed comparison of processes happening during the tick feeding with the situation in blood-feeding arthropods. Surprisingly, existence of separate routes for heme and iron has been found in ticks (Hajdusek et al. 2009) and will be further described in the following chapters.

Iron Metabolism

Iron is an indispensable inorganic compound for most organisms. It serves as an electron donor or acceptor in various metabolic processes and is a core component of many enzymes (iron or iron-sulfur clusters) involved, e.g., in the respiratory chain of mitochondria or DNA biosynthesis. Because of its importance (but also toxicity), its uptake, storage, utilization, and transport is in tick body maintained by a sophisticated mechanism. Ticks lack enzymes of the heme degradation (and also synthesis) pathway. This means that heme,

Tick: Iron/Heme Metabolism, Fig. 1 A scheme of tick iron and heme metabolism. Iron (*Fe*) or heme is released from the host blood proteins during the digestion in the tick midgut cells. Iron is intracellularly stored by the Ferritin1 (*FER1*) or transported into the tick tissues by Ferritin2 (*FER2*). Heme is detoxified by aggregation in hemosomes or transported into the tick tissues by Vitellogenin-like proteins (*Vg*)

released upon hemoglobin degradation in the midgut cells, cannot be enzymatically cleaved and iron deposited in the porphyrin ring (heme iron) doesn't serve as a source of iron for ticks. Therefore, it is obvious that other proteins, e.g., host transferrin or ferritin, must compensate the iron demand.

The host proteins are, similarly as hemoglobin, degraded in the tick midgut cell lysosomes. The released iron (nonheme iron) is likely reduced and transported into the cytosol, supplying the midgut cell with iron or being stored in the cytosolic protein called **Ferritin1** (homooligomers with storing capacity of 4,500 iron atoms and expressed in all tick tissues). Increasing concentrations of iron are sensed by the tick **Cytoplasmic aconitase1** (Iron regulatory protein, IRP), which post-translationally regulates synthesis of new molecules of Ferritin1 (by binding to Ferritin1 mRNA), balancing the level of "free" iron. To supply other tick tissues than midgut, the iron is loaded into **Ferritin2** multimers and secreted from the midgut cells into the hemolymph (tick blood). Ferritin2 then supplies other tissues, including ovaries, with iron, serving as an iron transporter (transferrin found in the tick genome

doesn't supply this function). Silencing of any gene from this iron metabolism cascade by RNA interference leads to the reduced tick feeding and developmental defect phenotypes.

Heme Metabolism

Heme, a prosthetic group containing iron in the center of porphyrin, is an indispensable component of hemoproteins involved in, e.g., oxygen transport (hemoglobin) or electron transfer. Similarly as iron, unbound heme evokes formation of toxic radicals with detrimental effects. As mentioned before, ticks are not capable of heme synthesis but demand heme for their own purposes. Thus, the host heme is well maintained and transported into peripheral tissues, mainly into the ovary, where it is stored in the eggs for embryonic and larval development. The main source of heme for ticks is obviously hemoglobin of the red blood cells. Heme released after hemoglobin degradation is transported from the digestive lysosomes into the cytoplasm and aggregated (detoxified) in specialized organelles called hemosomes. This process conspicuously remains

crystallization of heme in *Plasmodium*-infected red blood cells (hemozoin). The digestive cells full of hemosomes are released into the tick midgut lumen and directed into the waste. A small portion of heme (~10 %) is transported from the midgut cells and bound to the vitellogenin-like proteins abundant in the tick hemolymph. These heme-carrier proteins supply tick tissues with heme and transport heme and proteins into the ovary and developing eggs (maturing eggs are becoming brown). Similarly as for the iron metabolism pathway, silencing of heme metabolism genes by RNA interference results in the reduced fecundity.

Conclusion

Proper handling of heme and iron is crucial for the vast majority of organisms. The mechanism occurring in tick seems to be unique in many aspects and is worthy of other detailed studies. Blood-feeding arthropods including ticks greatly depend on the processes sequestering these compounds. As mentioned above, disturbance of these mechanisms by RNA interference blocks tick feeding and development. Vaccination of hosts (cows) with recombinant tick Ferritin2 has an adverse effect on tick (*Rhipicephalus* spp.) feeding and development (Hajdusek et al. 2010) and has a potential to replace or improve the current (the only commercial) antitick vaccine, which is based on the midgut protein called Bm86. Other tick proteins of the iron and heme metabolism should be tested for their possible antitick vaccination potential. Oxidative radicals released after incorrect processing of heme and iron could possibly impair also transmission of tick-borne diseases.

Tick-Borne Diseases: European Livestock Animals

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Food supply in people-rich countries in Europe is based on products obtained from cattle and other ruminants. Thus the tick-borne diseases of these animals are important factors for the market prizes of such products. Table 1 shows important agents of diseases and their vectors.

Tick-Borne Encephalitis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Synonyms

TBE.

General Information

Tick-borne encephalitis is caused by the TBE virus (► [Flavivirus](#), group B) which is also called Hypr virus. It is a disease clinically similar to ► [Russian spring-summer encephalitis](#). A frequent route of infection is oral, by drinking the milk of infected domestic animals. The main vector is *Ixodes ricinus*, a tick found throughout Europe, including Turkey, and the Atlas region of North Africa. The TBE virus has a tendency to spread westwards throughout the area of vector distribution. In Austria it is a serious menace and it has more recently widely occurred in West Germany, where mortalities were initially high. *I. ricinus* is also associated with ► [louping ill](#).

Prophylaxis

► [Vaccination](#).

Classification

Suborder of ► [Acarina](#).

General Information

The monoecious ticks may reach up to 2 cm in length and are vectors of important pathogens (viruses, bacteria, rickettsiae, anaplasms, ► [protozoa](#), and helminths; Table 2), since they feed on the blood of their hosts. Unlike ► [vessel feeders](#) (► [Mosquitoes](#)), tick mouthparts bring about more or less deep hollows in the host's skin, which become filled by blood of ruptured blood vessels (Fig. 1). Thus, the ticks are ► [pool feeders](#) engorging (in some species for minutes, in others for up to days) large amounts of blood (several times their body weights). During feeding, salivary secretions prevent blood coagulation. In some species (e.g., *Ixodes* spp., *Dermacentor* spp.) these injected substances are toxic and cause paralysis (tick paralysis), which may lead to death in humans and animals. In general, in all

Ticks, Fig. 1 DR of a feeding female ixodid tick. The arrows indicate pathways of wandering agents of diseases. Note that the tick engorges blood cells and lymph present within interstitial spaces of the tissues. A, anus; BL,

Ticks, Table 1 Differences between the two main families of ticks

Ixodidae	Argasidae
1. Cuticle is relatively hard	1. Cuticle is smooth and leathery
2. Scutum is present in all developmental stages covering the whole dorsal region of adult males but only the small propodosomal zone of larvae, nymphs, and adult females (<i>Ixodes</i>)	2. Scutum absent in all stages (<i>Argas</i>)
3. Capitulum anterior and always visible from dorsal view	3. Capitulum either subterminal or protruding from anterior margin of body in larval stages
4. Spiracles of tracheal systems are located behind fourth coxae	4. Spiracles between third coxae
5. Mostly one pair of eyes, if present, situated dorsally on sides of scutum. The eyes consist of a single cuticular lens (no eyes in <i>Ixodes</i> , <i>Haemaphysalis</i>)	5. Eyes are usually absent (if present, on supracoxal folds)
6. Larvae, nymphs, and adults suck only once for several days	6. Nymphs and adults suck several times (in general for minutes), whereas larvae engorge for some days
7. Only one nymphal stage occurs in life cycle	7. Mostly two nymphal stages occur; in some species up to eight are encountered
8. Males die after copulation which proceeds during the feeding act of females. Females die having laid the eggs on the soil (3,000 eggs in <i>Ixodes</i> , 6,000 in <i>Dermacentor</i> , 15,000 in <i>Amblyomma</i>)	8. Several copulation acts; several hundred eggs are laid on soil after each of the following feedings and copulation
9. Live mostly out of doors and only seldom in human dwellings; during life span species may attach consecutively to one to three hosts (species-specific; Table 2)	9. Live in farm houses, stables, nests of animals, etc., and attack their hosts during sleep

stages of the tick's life cycle (larvae with six legs, nymphs and adults with eight legs), it sucks blood. The life cycle of ticks is characterized by periods of starvation which can be of long duration and by relatively short periods involved with the uptake of enormous concentrated blood meals. The life cycle of an ixodid tick can often have a total duration of 6 years and host attachment may constitute less than 2 % of this time. Starvation periods of more than 3 years are common, and starvation can be particularly extended in some argasid tick species which have been known to survive for up to about 14 years. This ability is very important and has to be considered when dealing with the acute transmission and epidemiology of certain pathogens.

System

The ticks are subdivided into three families, namely, the ► *Argasidae* and the ► *Ixodidae*, to which most ticks belong, and the Nuttalliellidae,

which is a monotypic family characterized by features mainly intermediate to those of the two major tick families. The two major families, the “soft” *Argasidae* and the “hard” *Ixodidae*, can be differentiated according to the following biological and behavioral criteria (Table 1).

The more common genera of argasid ticks are *Antricola* (4 species), *Argas* (140 species), *Otobius* (2 species), and *Ornithodoros* (90 species). Ixodid ticks are further divided into two groups, the ► *Prostriata* and the ► *Metastriata*. Prostriata contains only the genus ► *Ixodes* which has about 250 species worldwide, while all other ixodid genera are classified as Metastriata. A distinctive difference between these two groups of ticks is the location of an anal groove anterior to the anus in Prostriata and posterior to the anus in Metastriata. The more important metastriate genera are ► *Amblyomma* (100 species), *Aponomma* (26 species), *Anocentor* (monotypic), ► *Boophilus* (5 species), *Dermacentor* (31 species), ► *Haemaphysalis* (150 species), ► *Hyalomma* (21 species),

Important Species

See Table 2.

Life Cycle

Argas/Life Cycle, ► *Ixodes* Species/Life Cycle.

Reproduction

In ticks the sexes are separate, but ► **sexual dimorphism** is less visible in the Argasidae than in the Ixodidae. In hard ticks, males and females have marked differences in the shape of the ► **scutum**, and females possess ► **porose areas** (with the exception of *Ixodes kopsteini*) which are not present in males. In the genus *Ixodes*, there is generally further dimorphism in the shape of the

gnathosomal appendages. Superficially, soft tick males and females are distinguishable by the shape of the sexual aperture alone. There are principal differences in the reproduction of the two main tick families.

Reproduction and Feeding

Reproduction in ticks is closely associated with feeding. This is of parasitological significance, since many pathogens of veterinary and medical importance are transmitted transovarially to the progeny of female ticks which have taken up the pathogens with their blood meal. Because many tick species can lay very large numbers of eggs, this mode of transmission can become the most efficient means of multiplying the pathogens (viruses, bacteria, rickettsia, or protozoans). Reproduction in ticks is therefore not only of direct interest for the maintenance of tick populations but also assumes a serious economic significance in relation to tick-transmitted diseases.

In argasid females, feeding and ► **oviposition** are cyclical activities which can be repeated several times (up to seven or more times). Mating can also be repeated in association with each female feeding. Mating can take place before or after feeding. Mated females digest the blood meal and oviposit, after which they are ready to repeat the process. Virgin argasid females, on the other hand, interrupt vitellogenesis until mating takes place, even if this does not occur for a long time. Unmated, engorged female *Ornithodoros moubata* can starve for up to 200 days before mating triggers off the completion of vitellogenesis and oviposition.

Autogenic development, i.e., the production of the next generation without the female feeding, has been reported in a number of argasid tick species. Facultative ► **autogeny** is usually exhibited during the first gonotrophic cycle when mated females lay eggs from which larvae hatch in the prolonged absence of a host, particularly in the case of ticks parasitizing seasonally migrant hosts. In the laboratory, autogeny can be induced in appropriate species under favorable conditions of temperature and humidity. Facultative autogeny has been observed in several species of *Ornithodoros* and *Argas*. The larvae of *Ornithodoros moubata* emerge from the egg and then remain quiescent until completing the molt to the nymph. In *Ornithodoros savignyi* some individuals complete the transformation from larvae to nymphs within the egg and emerge as nymphs. Obligatory autogeny is shown by two argasid genera with prolonged parasitic behavior, *Otobius* and *Antricola*. *Antricola* spp. females lack fully functional mouthparts. *Otobius megnini* has one parasitic larval and two parasitic nymphal instars which inhabit and do not leave the ungulate host's ear canals between blood meals, until the second nymphs leave the host and molt to the adult stages. Male and female adults both have vestigial mouthparts and do not take a blood meal. Mating takes place off the host and the female lays up to 1,500 eggs in small batches over a period of several months. Obligatory autogeny is similar in *Antricola* spp., where larvae and nymphs parasitize cave-dwelling bats, and females do not feed.

In ixodid ticks, larvae, nymphs, and females all take a single complete meal after which they molt to the next ► **instar**, except when the female lays a single batch of eggs and then dies.

Thus, feeding and oviposition are each single events in the lifetime of a female. Autogeny has not been reported in ixodid ticks. Mating is only possible up to the completion of feeding and is usually not possible prior to feeding. In most ixodid spp., mating takes place on the host only after attachment, but there are exceptions in the genus *Ixodes*, where in some species mating can take place prior to attachment to the host. In several species of *Ixodes*, the male is as yet unknown because mating apparently takes place off the host. The males appear either not to feed, or to feed parasitically on engorged females. Male *Ixodes holocyclus* and *I. moreli* have been shown to engage in homoparasitism, during which they feed on the hemolymph of partially or fully engorged females of the same species which appear to be unaffected. This may be an obligate form of male feeding in these and other ixodid species. Nymphs and males of *Argas* spp. and *Ornithodoros* spp. can also feed on the hemolymph and/or midgut contents of engorged individuals of their own species.

In contrast to oogenesis, a large part of gametogenesis is not closely correlated with adult feeding. After the initial development, formation is discontinuous depending on adulthood and the transfer of germinal cells to the female genital system. Argasid ticks (*Argas*, *Antricola*, *Ornithodoros*, and *Otobius*) undergo spermatogenesis prior to feeding as adults.

Reproductive Organs

The **female** genital systems of ixodid and argasid ticks are basically similar, consisting of a single ovary with paired oviducts which fuse to become an unpaired common oviduct or uterus (*Argas vespertilionis*, possessing a paired ovary, is an exception). The uterus opens into the vagina which is divided into cervical and vestibular regions (Fig. 2). The ovary of the tick is a hollow, tubular, thin-walled organ with a horseshoe-

Ticks, Fig. 2 DR of acarine reproductive systems. (a–c) Females, (d–f) males. (a) Generalized system Gamasida and Actinedida; (b) Acaridida, Acaridae; (c) Ixodida,

Argasidae; (d) Gamasida, Parasitidae; (e) Gamasida, Uropodidae; (f) Actinedida, Erythraeidae

shaped cross section due to a fold or longitudinal groove along the dorsal or anterodorsal surface. The unpaired ovary forms a garland-like continuous loop through most of the length of the unfed female, beginning anteriad at the level of the central nerve mass or genital aperture and extending posteriad near the sides of the tick to curve forward in front of the rectal sac. At the peak of egg production, it is the most prominent organ in the female ixodid tick. It is made up of thin layers of epithelial cells with interspersed germinal cells and a basement lamina or tunica propria which forms the external, hemocoelic surface of the organ. Germinal cells are least developed in the longitudinal groove where oogonia and early oocyte stages are found. Outside the groove, the ► **oocytes** are generally more

advanced and give the ovary a granular appearance (Fig. 3). When the tick starts feeding, oocytes covered by the basement lamina protrude into the hemocoel. The ovary then has a characteristic grapelike surface structure. In members of the Argasidae, the posterior part of the ovary is studded with oocytes while the anterior part is smooth, whereas in members of the Ixodidae, ova develop along the whole length of the organ.

At both ends, the ovary tapers and passes into long, coiled oviducts running in an anterior direction. The oviducts are elastic tubes capable of peristaltic movements which serve to transport eggs toward the uterus and vagina. The oviduct is capable of stretching in order to accommodate eggs. In argasid ticks, the distal oviduct forms a distinct ampulla, but this is less pronounced in

Ticks, Fig. 3 Cross section through the ovary of an ixodid tick showing eggs in nine different stages of development. At place 9, the mature fertilized egg is released into the lumen to become set free. Note that the eggshell is thin in stages 1–4; until then fertilization and infection with parasites/virus/bacteria may occur. DS, development of eggshell; E, egg; ES, eggshell; LL, lumen of body cavity; LO, lumen of ovarian tube; N, nucleus; OC, oocyte; R, nucleus after karyogamy; ST, funiculus; ZG, young oocyte in a groove (After Sonenshine)

ixodid ticks. Distally, the oviducts fuse into a single common oviduct or uterus; this is a large bilobed triangular sac in argasid ticks, smaller in the Prostria, and inconspicuous in the Metastriata, where a separate ► [receptaculum seminis](#) takes over the function of storing the spermatophores and spermatids. In argasid ticks, these are stored in the uterus. The uterus is connected by a short tube to the cervical region

of the vagina. This is short in argasids but is an enlarged saclike structure in prostria, where it functions as a receptaculum seminis.

The receptaculum seminis of metastriates is above the uterus and opens directly into the cervical vagina which is the proximal portion of the vagina as opposed to the distal, vestibular portion of the vagina. In argasid ticks, the cervical vagina is short. It is ensheathed with a thick layer of circular muscles. In all ticks, the vestibular vagina connects the cervical vagina to the genital aperture and is capable of prolapsing actively during oviposition when it plays a significant role as an ovipositing tube. Tubular accessory sexual glands are present in all ticks. They have openings between the two regions of the vagina and are presumed to coat eggs with secretory products as they pass prior to expulsion. The lobular accessory sexual gland, which is only found in ixodid ticks, is formed in the vestibular vagina from the hypodermis during feeding. Its secretion partially waterproofs eggs during their passage through the vagina.

► [Géné's organ](#) is common to all female ticks. It is found just above where the capitulum is joined to the ► [idiosoma](#), in the camerostomal fold of ixodid ticks, the camerostomal depression of argasid ticks, or anterodorsally ventrad of the pseudoscutum in nuttalliellids. During oviposition, Géné's organ emerges through an aperture to give each egg a waxy surface, as a final waterproofing. The porose areas of female ixodid ticks (Fig. 6), whose function was not known for a long time, appear to act in conjunction with Géné's organ by producing inhibitors of the autoxidation of the unsaturated egg wax lipids.

The morphology of the female reproductive organs of the single species in the family Nuttalliellidae, *Nuttalliella namaqua*, is basically intermediate between corresponding argasid and ixodid organs. The transverse position of the ovary, bilobed uterus, and vaginal divisions into cervical and vestibular parts are as in argasids; however, the connecting tube joining the uterus and cervical vagina and the valve between the vaginal divisions are ixodid in character. On the other hand, Géné's organ has a structure unique to this family.

The **male** reproductive system consists of paired tubular testes which extend from the level of the central nerve mass or genital aperture to about the level of the posterior margin of coxa IV (Fig. 2). Apically, the testes extend to become a pair of vasa efferentia which fuse to form a common vas deferens and ejaculatory duct.

Posteriorly, the testes may be fused (as in the Argasidae), broadly joined (as in many prostriate ticks), or connected only by a thin filament (as in the metastriate ticks). The testes in adults are covered by a thin connective tissue membrane similar to the tunica propria of the ovary. There are muscle fibers under the membrane. The wall of the ► **testis** consists of epithelial, interstitial, and germinal cells. The germinal cells are arranged radially around the small lumen of the testis, forming cysts. The lumen of the testis is continuous with the lumen of the vas deferens. The appearance of the testes varies with the tick species and its nutritional and reproductive state. In particular, there are marked changes in the testes of ixodid males when they commence feeding.

The vasa efferentia are extensions at the end of the testes which fuse to become the common vas deferens whose connection to the external genital

aperture is called the ejaculatory duct, a name sometimes also given to the common vas deferens as a whole.

Close to the fusion between the vasa deferentia, the accessory gland complex opens into the common vas deferens (Fig. 2). This is a large, multilobed gland system which varies in appearance between tick species. The accessory gland secretes mucoproteins, mucopolysaccharides, and other compounds. The glands are involved in producing materials for ► **spermato-**
► **capacitation**.

Spermatogenesis and Fertilization

The testes in ticks are fully developed at the end of nymphal molting. In contrast to insects, male germinal cell maturation occurs gradually from the posterior end to the anterior end of the testes. In *Hyalomma asiaticum* nymphs, primary spermatogonia areas occupy the anterior end of the testes and secondary spermatogonia areas the posterior end. Primary spermatogonia undergo mitotic divisions to produce several generations of secondary

spermatogonia, the last generation becoming primary spermatocytes during nymphal blood feeding. In *H. asiaticum*, as in most other metastriate ixodid ticks, further development only occurs when the adult males begin feeding. Autogenous spermatid production in unfed males has been reported in two metastriate ticks, *Aponomma hydrosauri* and *A. concolor*. A third species *Amblyomma triguttatum* transfers elongated spermatids to females without a prior blood meal.

The timing of meiosis and spermiogenesis in the argasid and prostriate ticks is similar to that in most insects, occurring maximally during the final nymphal stage and the young adult period, i.e., prior to feeding as adults. Males of many

prostriate ticks (genus *Ixodes*) do not feed at all. The same occurs in those species of argasid ticks which have vestigial mouthparts in the adult (*Otobius* spp.). A blood meal accelerates the germinal development.

Thus the male adult blood meal is the foremost stimulus for development of the primary spermatocyte stage in most metastriates. Other, earlier stimuli are active in the males of prostriate and argasid ticks. As a result of the stimuli which are effective, the spermatocyte undergoes a major growth stage, followed by two meiotic divisions to secondary spermatocytes. Newly formed spermatids are rounded and are found in the testes. Further development takes place as they move to

the vasa deferentia and then to the common vas deferens, by which time they have an elongated form. Here they are stored until transfer to the female takes place through mating. Development is arrested at this point. Then the male transfers a spermatophore to the female. This is not preformed but is produced during mating. The formation is a rapid process, requiring less than 1 min to complete, and it occurs outside the male genital aperture. The spermatophore consists of two vessels, i.e., an outer (Ectospermatophore) and an inner (Endospermatophore) container between which the elongated spermatids are to be found.

When both sexes are prepared for copulation, the male tick positions himself with his venter in juxtaposition to the female venter and inserts certain parts of the capitulum (varying between species) into the female sexual aperture. After this

initial stimulation, which lasts some minutes, the spermatophore is formed and transferred to the female sexual aperture. Through evagination of the spermatophore only the endospermatophore is inserted into the female genital tract during copulation; the spermatids are contained only in the endospermatophore, while the ectospermatophore remains outside and soon drops off. The spermatophore is easily visible at the genital aperture of freshly mated *Amblyomma variegatum* females which are then no longer receptive for further stimuli from male ticks, which are themselves not attracted to these females. Mating triggers off an immediate feeding response in the females, regardless of the presence or absence of males. In this state, female *A. variegatum* can then be induced to feed in an in vitro system.

In argasid ticks, endospermatophores and immature (uncapacitated) spermatids are stored

Ticks, Fig. 7 (a, b) TEMs of the cuticle of acarids. (a) Ixodid tick (*Ixodes ricinus*) ($\times 2,000$). (b) Mite (*Bdellonyssus* sp.), which contains a second stage larva (in cross section) of the rodent filarial worm *Litomosoides*

in the uterus, while in ixodids they are transferred to and stored in other regions of the female genital tract: in the Prostriata, this is the enlarged cervical vagina, and in the Metastriata, it is a separate receptaculum seminis which opens posterodorsally into the cervical vagina. The last stage of spermiogenesis, capacitation, then takes place within the female genital tract. The fully mature, or capacitated, **spermatozoa** are clavate or paddle-shaped at the anterior end, tapering into long posterior portions. Argasid sperm are longer than those of ixodids. The spermatozoon is 150–1,000 μm long which is twice the length of uncapacitated spermatids. This is extremely large by comparison with the spermatozoa of other animals.

Oogenesis

The surface of the tick ovary has a characteristic granular appearance which is caused by the partial protrusion into the hemocoel of the oocytes (Fig. 3). The oogonia and oocytes are less developed in the longitudinal groove along the ovary. As the female begins feeding, the oocytes protrude more into the hemocoel, above the surface

of the ovary. They gradually project further until they are totally above the surface of the ovary, to which they remain attached by a thin stalk, the funicle, which is composed of elongated epithelial cells. Covering the oocytes and the ovary and separating them from the hemolymph is a basement lamina, which carries some muscle fibers on the outside. Balashov has divided the early previtellogenic development into a phase of “small growth” followed by a phase of “large growth” with cytoplasmic growth, which is characterized by intense development of cytoplasmic organelles almost entirely lacking during the first phase. During cytoplasmic growth, the surface area of the oocyte cellular membrane is greatly enlarged by the production of numerous **microvilli** below the basement lamina in preparation for further maturation of the egg. Vitellogenesis, the production of **yolk** as a nutrient for the developing larvae, is usually initiated by engorgement and mating, except in cases of autogeny or **parthenogenesis** as discussed above. The final product of vitellogenesis is represented by two kinds of yolk, protein and lipid. Lipid yolk is produced during the previtellogenic period but protein yolk is a characteristic of vitellogenesis, appearing as the membrane-limited granules

Ticks, Fig. 8 DR of the acarine cuticle. *N*, nucleus; *P*, pore channel

shown in *Omithodoros moubata* to be composed of hemoglycolipoproteins which are immunologically identical to female hemolymph proteins. The yolk appears to have two different sources, intracellular from autosynthesis in the oocyte and extracellular from synthesis in extraovarian tissues of precursors which are internalized by the developing oocytes. Protein yolk vesicles fuse to form large homogeneous yolk granules with a diameter of up to 80 μm in the egg of *O. moubata*, which itself has a diameter of 1,200 μm .

The source of the vitelline membrane has not been ascertained but appears to be the oocyte. Eggshell synthesis begins during vitellogenesis, when plaques of material appear between the microvilli of the ► [cell membrane](#) in the extracellular space under the basement lamina. As development advances, the microvilli become fewer and retract, while the eggshell plaques coalesce to form a complete vitelline envelope. From a certain point onwards, the vitelline membrane

and the basement lamina appear to act as a barrier to the entry of pathogens which take the transovarian route of transmission. This has been shown for *Babesia major* kinetes in *Haemaphysalis punctata*, *B. bigemina* in *Boophilus decoloratus*, and in rickettsia. Although 28 °C is a favorable temperature for the rapid development of *B. bigemina* kinetes in *Boophilus decoloratus*, only very few appear to be able to enter the oocytes which become impenetrable sooner at this temperature; at 24 °C, fewer kinetes are found in the hemolymph since a greater number are able to enter the oocytes before they become impenetrable (Fig. 3).

The success of ► [transovarial transmission](#) of parasites appears to be dependent on close synchronization with the development of the tick vector, and may be a reason for the more efficient transmission by some vectors. For example, *Boophilus microplus* appears to be a less efficient vector for *Babesia bigemina*, but a good vector for *B. bovis*.

The oocytes in the ovary of a tick do not develop synchronously but can be found at different developmental stages at any time. As a result, vitellogenesis and oviposition are prolonged over several days or weeks in ixodid ticks.

Ovulation in ticks usually takes place within 1–2 weeks after the fertilized female has engorged. Following ovulation, peristaltic movements of the genital tract transport the eggs into the uterus where they can accumulate. The actual site of ► [syngamy](#), i.e., the penetration of the oocyte by the sperm, has not been determined, and it may take place in the ovary or in the oviducts. During its passage, the oocyte increases greatly in size and the originally soft, extensible eggshell hardens progressively.

Oviposition

Generally, argasid females lay fewer eggs than ixodid females. *Argas persicus* can lay a total of 874 eggs in as many as seven batches, with a blood meal and mating preceding each batch. *Ornithodoros coriaceus* can lay over 2,000 eggs during a productive life of about 3 years.

Ticks, Fig. 9 DR of the salivary gland of an ixodid female tick. (a) Overview on one branch of the salivary glands. Agranular (AA, black) and granular (GA) ► acini are grouped grapelike around the twisting salivary duct (SP). AS, portion being magnified in b. (b) Cross section of an acinus of type III including granular cells of type D, E,

F with different contents. After release of the secretory granules, the cell becomes replaced by interstitial cells. Before oviposition can begin, the fully engorged females usually become positively geotropic and negatively phototactic, seeking sheltered places with a suitable microclimate. The female then becomes immobile. The preoviposition period of engorged female ticks lasts from 1 to 2 days up to several weeks depending on species and temperature. In *Boophilus microplus*, this period is 2–4 days in the Australian summer and 5–9 days in winter, with a range of 2–12 days. On the periphery of the main area of distribution, in Southeast Queensland, oviposition is postponed indefinitely. Oviposition may be so far extended that many females die before ovipositing. The duration of oviposition is also dependent on the species of tick and the environmental temperatures and can last from a few days to several weeks.

Oviposition entails the individual treatment of each egg as it is laid. In ixodid ticks, this requires a reorientation of the genital aperture to face the capitulum at an angle and to shorten the passage

of eggs. In argasid ticks, this does not take place, but otherwise oviposition is similar in both tick families. The next step is to bring the Gén 's organ close to the sexual aperture. Gén 's organ, the egg-waxing organ, is located in the camerostomal fold of ixodid ticks or the camerostomal depression of argasid ticks, dorsally behind or above the capitulum where it is joined to the idiosoma. It is an eversible two- or four-lobed sac with two anterolateral horns on each side. When eggs are about to be extruded from the vestibular vagina, the ► hypostome is depressed ventrally to such a degree that it rests against the venter of the tick, while the palpi diverge. As Gén 's organ becomes fully everted, the vestibular vagina prolapses, forming an ovipositing tube through which the individual eggs are passed; they then pass between the horns of the Gén 's organ. While the vagina retracts, the oocyte is thoroughly coated with waxy waterproofing secretions. In ixodid ticks, each oocyte is simultaneously exposed to a

Ticks, Fig. 10 SEMs of mouthparts of ixodid ticks. (a) View from the dorsal side in a larva of *Ixodes ricinus*. $\times 150$. (b) View into the mouth (M) of *Amblyomma variegatum*. Note the teeth at the hypo- and epistome. $\times 400$. C, chelicera; M, mouth; P, pedipalps

secretion from the porose areas during the period in which the Gén  s's organ covers this area of the capitulum. This additional secretion appears to inhibit the autoxidation of unsaturated egg-wax lipids. In argasid ticks, waterproofing of the eggs is begun in the vestibular vagina. The eggs of argasid ticks are usually not sticky, while ixodid eggs adhere to the surfaces they rest upon. This can be upon the female tick's dorsum.

The ovipositing female of many ixodid species changes color, becoming yellowish or pale brown due to the masses of developing oocytes, on the one hand, and the grossly distended Malpighian tubules, on the other hand. Most of the metabolic waste is not eliminated by the female and may be responsible, together with ► [dehydration](#), for the

death of the female ixodid tick soon after completion of oviposition.

The eggs of ixodid ticks are toxic to experimental animals, as are ovipositing female ticks. On the other hand, fully engorged female *Amblyomma variegatum* (which can have an engorged weight of up to 6 g) are consumed by herdsmen in parts of East and Central Africa, either raw or after roasting, and are considered a delicacy.

Pheromones

Contact between sexes and behavioral patterns leading up to copulation appear to be strongly

influenced by pheromones. In ticks, which mate off the host (i.e., argasid and some prostriate ticks), assembly pheromones, which are the least specific of the tick pheromones, appear to be responsible for bringing together males and females. These pheromones are also attractive to immature instars, e.g., in *Argas persicus*. The relationships between individuals of *A. walkerae* in the biotope are mainly induced by pheromones. Replete females determine the location of settlement, thereby sending the primary pheromonal stimulus attracting first males and then preimaginal stages to aggregate. Guanine excretions have a lesser pheromone effect. The assembly pheromone in guanine is less volatile than that emitted by the tick itself. In *Ornithodoros porcinus porcinus*, the guanine itself has been identified as an assembly pheromone which not only attracts conspecific ticks but is also attractive for larvae of *Amblyomma cohaerens* and adult *Rhipicephalus appendiculatus*.

A second type of pheromones, the ► **aggregation-attachment pheromones**, have been demonstrated in the metastriate genus *Amblyomma*, where they are produced by males during the course of feeding. They are more specific than assembly pheromones and attract conspecific unmated females, unfed males, and nymphs. Hungry unmated females are reluctant to attach in the absence of this powerful stimulus. It is possible to induce mating in *A. variegatum* by removing males from the host after several days of feeding and placing them together with unfed females. Mating responses are immediate, culminating in copulation within a few minutes, after which the female is no longer receptive for males but will commence feeding, frequently in the complete absence of a male. In this species, the primary stimulus leading to contact appears to be the male aggregation-attachment pheromone, followed by a response from the female (which may be recognized visually, or possibly chemically, by the male), whereupon the excited male agitates its striped legs, grasps the female, corrects her position if necessary, and then proceeds to insert his mouthparts into the genital opening and transfer the spermatophore.

The aggregation-attachment pheromones have been identified, the active substances being *o*-nitrophenol, methyl-salicylate, and pelargonic acid. Pheromones are usually obtained for study by washing intact ticks in suitable solvents or by extraction from tick homogenates. They can also be collected from living ticks in small stainless-steel chambers when the effluent air is passed through solvents. The site of pheromone production in ticks has therefore remained difficult to determine. In a field trial, synthetic pheromones were only partially successful in attracting ticks to an artificial target.

Integument

Ixodid or hard ticks are characterized by a dorsal shield or scutum of sclerotized ► **cuticle** in all stages which occupies about one-third of the anterior dorsal surface of females, nymphs, and larvae and the entire dorsal surface of males (Figs. 4, 5, and 6). In female and immature ixodid ticks, the remaining, extensible dorsal surface is called the ► **alloscutum**. Argasid ticks are also called soft ticks, since they lack a scutum or dorsal shield in the adult stages and are covered by a leathery ► **integument** (Fig. 6).

In addition to exoskeletal functions of support and protection, the integument of ticks, particularly of ixodid ticks, is required to grow and expand in order to accommodate the large and concentrated blood meal. In ixodid ticks, the differences in size between larvae, nymphs, and adults are not as great as the differences between the flat, unfed instar and that same instar fully engorged. Larval, nymphal, and female ticks of some species of ixodid ticks can increase in weight up to about 200-fold during feeding. As an example, *Rhipicephalus appendiculatus* larvae, nymphs, and females can each increase their weight about 100-fold. During the blood meal, the idiosoma of these stages is distended to give the typical enormously swollen appearance of the engorged tick. An additional important function of the integument of ticks is the regulation of water balance since it is highly impermeable to water.

The cuticle constitutes a limitation of the shape and maximum size of each tick stage. Further growth is only possible through molting of the preimaginal instars, i.e., by shedding the cuticle and replacing it with the larger form of the next stage.

As in other arthropods, the integument of ticks consists primarily of the cuticle and a single epidermal cell layer which secretes the cuticle. The cuticle is similar to that of insects (Figs. 7 and 8, ► [Insects](#)), but differences exist, particularly in the alloscutum of female ixodid ticks. The cuticle is a heterogeneous, noncellular layer which forms an external covering but also extends into the fore- and hindguts and lines the ducts of dermal glands and the tracheal system. The degree of sclerotization of the cuticle varies from hard sclerotized plates to soft, extensible membranes. Ixodid ticks have relatively large areas of sclerotized cuticle, while in argasid ticks sclerotization is limited to fairly small areas.

The cuticle is composed of two primary layers, a thin outer epicuticle and the thicker inner procuticle. The epicuticle has considerable flexibility but is nonextensible in ixodid ticks. Stretching during feeding is possible through the unfolding of deep folds in nonsclerotized areas of the idiosoma of the ixodid tick. The epicuticle is nonchitinous and consists of wax, ► [cuticulin](#), and polyphenol layers. Argasid ticks also have a further outermost protective layer, the cement, a general arthropod characteristic which is absent in ixodid ticks. The cement is produced by dermal gland secretion. The wax layer confers impermeability on the cuticle. In ixodid ticks, this is the outermost layer. Beneath it, the polyphenol layer is composed of minute droplets rich in polyphenols which penetrate into the underlying cuticulin layer. A thin protein or lipoprotein membrane carries large numbers of ► [micropores](#) connected to pore canals which themselves originate in the epidermal cell layer and pass through the procuticle, anastomosing terminally before reaching the cuticulin. In *I. ricinus* it has been estimated that more than 1.4 million pore canals can be found per square millimeter (Fig. 7). Dermal glands become active soon after feeding begins, remain so until molting is complete, and

are thought to participate in cuticular transformation.

The procuticle is composed mainly of ► [chitin](#) bound to protein and can show differing degrees of sclerotization. When the outer part of the procuticle is completely sclerotized, it is called exocuticle, and the nonsclerotized portions are then called endocuticle. The mesocuticle is defined as a partly sclerotized layer of the procuticle. Both the endo- and the mesocuticle, which form the alloscutum cuticle, are extensible and enable the accommodation of the large blood meal in larval, nymphal, and female ixodid ticks, through their capacity for expansion and stretching. The increase in the volume of the tick is particularly rapid during the final feeding period and is achieved by considerable stretching of the alloscutum. This is made possible during the initial feeding period through preparatory growth of the cuticle, enabling the phase of rapid feeding. During the first phase of feeding, growth of the cuticle dominates over expansion, while at the end of feeding, when ingestion reaches a peak, idiosomal distension occurs as a result of cuticular extension.

During the growth period, procuticle with a complex lamellate structure is deposited. At the same time, epidermal cells enlarge three to four times, with rapid development of organelles involved in synthesis. In argasid tick larvae, which feed for several days, there is also cuticle thickening during the growth phase. During the final phase of ixodid female feeding, the cuticle of the alloscutum stretches and is reduced to about half the thickness reached at the end of the growth phase.

During molting (► [Ecdysis](#)), a phase of cuticle separation (► [Apolysis](#)) is followed by formation of new cuticle and shedding of the previous cuticle. Separation results from lysis of the procuticular lamellae closest to the epidermis. In the new cuticle, epicuticle is formed first and then procuticle.

Hemocyte participation in the molting process is peculiar to ticks. During the premolting period, apolysis and the early stages of new cuticle formation, numerous hemocytes lie under the epidermal cell layer, sometimes penetrating into the epidermis.

Musculature

Ticks are typically acarine in having hexapod larvae and octapod nymphs and adults. The legs are jointed and divided into seven segments (coxa, trochanter, femur, genu, tibia, tarsus, and pretarsus). The terminal pretarsus consists of a basal stalk, paired claws, and a membranous pulvillus (Figs. 4 and 6). The pulvillus is absent in argasid ticks. Each true segment is flexed by an individual flexor muscle, while coxal protractor and retractor muscles provide backward and forward leg movement. Leg extension is brought about by hydrostatic pressure. All legs are ambulatory, but the first pair of legs also ► [aids](#) in sensory ► [orientation](#).

Powerful muscle groups are also present in the alloscutum of female, nymphal, and larval ixodid ticks, through which the tick is able to redistribute the center of gravity and regain an upright position when it falls into an upside-down position. The dorsoventral muscles are arranged roughly in longitudinal rows. The point of insertion is characterized only by shallow furrows or grooves.

The major organ systems and the ► [chelicerae](#) are equipped with muscles, most of which only play a role during the short periods of host-orientated activity and the following digestive and/or ovipositing periods.

The structure of muscle attachment in ticks must make allowance for the periods of molting from one stage to the next, particularly when the muscle is attached to the cuticle. By means of the electron microscope, muscle attachment has been shown to be through a structure characteristic of other arthropods. ► [Tendons](#), or tonofibrillae, by which the muscles are attached, consist of two sets of tonofibrillae which are not continuous from the muscle to the epidermal cells of the cuticle. One set of tonofibrillae is anchored to the internal faces of muscle cells, while the second set is attached to the epidermal cells. The intercellular spaces between tonofibrillae are filled with a cement-like substance. The anchorage at both the proximal muscle cells and distally the epidermal cells is through structures known as ► [hemidesmosomes](#), which are adhesions between the basal lamina through the plasma membrane to the

► [cytoskeleton](#). Similar arrangements are found in ► [mites](#) (Fig. 7b, ► [Mites](#), Fig. 1).

Alimentary System

The entrance to the alimentary canal, the tubular buccal canal, is formed dorsally by the chelicerae and ventrally by the hypostome (Figs. 4 and 9). These two parts of the gnathosoma form the anchorage of the tick to the host skin during feeding. The chelicerae are paired, sheathed, rigid, sclerotized tubes with two segments (other acarians have three segments) ending in cutting digits with recurved teeth with which the tick penetrates the host skin (Figs. 9 and 10). The unpaired hypostome is an extended, toothed anterior process of the basis capituli with retrograde denticles on the ventral surface. In ixodid ticks with the exception of some *Ixodes* spp., the feeding channel is further sealed during host attachment by attachment cement, a salivary gland product which solidifies almost immediately, making the tick alimentary canal continuous with the lesion in the host skin. The cement seals off and firmly embeds the mouthparts (Food Uptake and Digestion). If some tick species are removed manually from the host, the cement often remains attached to the mouthparts.

The buccal canal is a common duct for the intake of host tissues and for the outflow of saliva. It passes into the pharynx, a powerful suction organ with several sets of constrictor and dilator muscles, which, in conjunction with the pharyngeal valve, moves host tissues into the esophagus. The esophagus, a narrow tube adjoining the pharynx, passes through the synganglion or “brain” (as in other acarians) before leading to the midgut or ► [ventriculus](#). This consists of a large central chamber from which several pairs of blind-ending diverticula or ceca lead off, providing additional surface area on which digestive processes can take place. Some are branched or form numerous loops. The midgut fills most of the body cavity of the tick. It is well equipped with muscle fibers situated externally and arranged both longitudinally and transversely, and it is capable of peristaltic and other movements. When the leg of a

tick is cut off, as in investigations for hemolymph stages of ► *Babesia* spp. or ► *Theileria* spp., the hemolymph is frequently mixed with gut contents because ceca protruding into the leg are also damaged.

The midgut has a fairly uniform structure throughout, the wall consisting of a single epithelial cell layer resting on a thin basal lamina, with muscle fibers on the hemocoelic side. According to Balashov and Sonenshine, three types of cells are present in the epithelium: reserve or stem (undifferentiated) cells, secretory cells, and digestive cells. Agdebe and Kemp described intermediate digestive cells (digestive cell series) and two different secretory cells in *Boophilus microplus*. There are indications that each cell can differentiate successively to serve both secretory and digestive functions, particularly in argasid ticks. In ixodid ticks, it appears more likely that each cell differentiates irreversibly to take either a secretory or a digestive role. The apical or luminal surface of epithelial cells is covered with microvilli, while the distal plasma membrane is folded until the time when the tick begins ingesting blood. Because of projecting epithelial cells, the midgut lumen is small.

A short intestine (sometimes called the small intestine) joins the midgut to the rectal sac. It is a tube narrowing towards the rectal sac which it enters anteroventrally. In the rectal sac, the fecal discharge accumulates, together with the products of the Malpighian tubules, to be expelled through the anus.

In ixodid ticks the salivary gland plays a major role during feeding, and it is also of importance for the development of a variety of pathogens, many of which conclude their development there before being transmitted to the host. The role of the salivary gland in argasid ticks is different, the excretion of fluid into the host during feeding being minimal. In ixodid ticks, salivary excretion into the host animal body is responsible, to a large extent, for preventing the excess dilution of the tick body fluids by eliminating the major part of the blood meal's liquid content (Food Uptake and Digestion). It has been the subject of extensive studies, both by light and electron microscopy.

The salivary gland is a paired organ with a similar appearance in both sexes (Fig. 9). It consists of grapelike clusters of acini extending from the level of the peritremes along the sides to the gnathosoma, where the paired main ducts open into the salivarium, which opens dorsally into the buccal canal.

In argasid ticks, two types of acini are present, while in ixodid ticks, there are three in females and four in males of some species. Type I acini are agranular and are confined to the anterior region of the gland, where they open directly into the main or secondary ducts (Fig. 9). In *Hyalomma asiaticum*, type I acini contain several nuclei, one of which is considerably larger than the others. In *R. appendiculatus*, four types of cells are found. The peripheral cells show densely compact foldings of their plasma membranes to and from the basal lamina, forming a basal labyrinth, and interdigitate with the peripheral plasma membranes of the central cell with its large nucleus. A ring-shaped constrictor cell surrounds the acinar duct which is also formed by the neck cell. The structure is thought to be responsible for secreting hygroscopic salts required for the active uptake of atmospheric moisture by nonparasitic stages. The acinus type I shows little change during feeding. Type II acini in argasids show two or three cell types in different species. In ixodid ticks, the granular types II-IV acini show marked changes during feeding. Up to ten different granular cell types are found. The granules are sometimes complex in structure. Type II acini increase in size and secretory activity during feeding and can dominate in late feeding. As in type III and IV acini, cells are arranged in radial segment fashion around the lumen which leads to the duct, passing a valve (argasids do not have a valve). There is no clearly proven association between structure and function of cells in granular acini, some of which pass through a rapid sequence of synthesis, secretion, and hypertrophy. This sequence is asynchronous between cells. The type IV acinus of *R. appendiculatus* males continues development after the first mating and may reach its maximum size several days after the female has dropped. All acini types include a variety of secretory cells, the products of which

fulfill different tasks such as lytic, anesthetic, anticoagulant functions.

Food Uptake and Digestion

Feeding Habits

All ticks are obligate ectoparasites of mammals, reptiles, or birds. Depending on their host relationships, ixodid ticks can be referred to as one-, two-, or three-host ticks, while most argasid ticks can be referred to as multihost ticks. These feeding habits are of ecological interest as well as of significance in disease transmission and control of ticks. The larvae, nymphs, and adults of one-host ticks all feed and molt on the same host. Ticks of the genus *Boophilus* are such examples where larvae attach to bovines and engorged females drop off the host 3–4 weeks later. Except for the engorged female, all stages are very small. The genus *Margaropus* also includes one-host ticks. Acaricide resistance in ticks is particularly prevalent among one-host ticks (*Boophilus*) where selection pressure is directed against all stages and heritably resistant mutant individuals have a greater chance of survival and of becoming the progenitors of resistant populations. In the two-host ticks, larvae feed and molt without leaving the host, the replete nymph dropping and molting on the ground. The adults then seek a second host to complete development. *R. evertsi*, with two subspecies, is a two-host tick found throughout sub-Saharan Africa. Some species of *Hyalomma* are also two-host ticks and among them are ticks which can use two or three hosts in different generations. The majority of hard ticks require three hosts to complete development, each stage becoming replete on a host and then dropping to the ground to molt. Larvae, nymphs, and adults each seek a different host, the engorged female dropping from the third host to lay eggs on the ground. Seasonal and regional variations in the prevailing microclimate conditions of three-host ticks can result in life spans of 2 or 3 years in *Dermacentor andersoni* or even up to 6 years in *I. ricinus*, in cool climates.

In two- and three-host ticks, the different stages may prefer completely different host species. In

many three-host ticks, larvae and nymphs prefer small rodents and lagomorphs as hosts while adults attack larger mammals. In some cases, the larvae and nymphs of a species are unable to survive on the host species of the adults.

The argasid ticks have different feeding habits from hard ticks, with usually much shorter feeding periods and up to seven nymphal feedings (*Ornithodoros coriaceus*) as well as up to seven meals in the adult stage (*Argas persicus*), with a different host each time. Ticks with these feeding habits can be termed multihost ticks. *Otobius* spp. are exceptions, showing a modified one-host pattern of feeding.

Ticks show a varying degree of host specificity. This varies from the very wide range in ticks such as *Ixodes ricinus* (mammals, birds, reptiles) to preferences for smaller groups such as in the *Haemaphysalis leachi* group which prefers carnivores, and finally to very high specificity, sometimes involving a single host such as is found with *R. simpsoni* on the cane rat. On the host, many tick species choose more or less specific sites, usually for strategic rather than other purposes. In East Africa, ticks with long mouthparts and very painful bites (*Amblyomma* spp.) prefer the perianal and inguinal regions where the host cannot reach them and where they are safer from predating birds of the genus *Buphagus* (► **Oxpeckers**). Specific sites in adult ticks are also likely to improve the chances of finding a mating partner.

Ticks are reluctant to feed on an unusual host. If they do feed, they take up smaller quantities and concentrate the components to a lesser degree. Out of five mated rhinoceros tick (*Amblyomma rhinocerotis*) females engorged on a bovine, only three laid eggs, of which only one batch hatched. The resultant larvae refused a variety of laboratory hosts.

In ticks, reproduction and feeding are often closely related. However, there are many cases of larval and adult ticks not requiring a blood meal for further development (Reproduction and Feeding). In many prostrate species, the male does not feed.

As a rule, the period of feeding is short in argasids and long in ixodids. In most species of *Argas* and *Ornithodoros*, adults and nymphs do

not require more than 15–60 min to engorge, the range being approximately 2 min to 2 h. Larvae of argasid ticks require longer feeding times than the corresponding nymphs and adults. *Argas persicus* and *A. reflexus* larvae require 5–10 days and *A. boueti* 16–25 days. During engorgement, soft ticks ingest quantities of blood corresponding to three or four times their original body weight. In hard ticks this quantity can be 50–200 times the weight of the unfed female. They remain attached to the host and engorge in 5–12 days, unless they do not mate, in which case they may remain for several weeks. Larvae and nymphs of *R. appendiculatus* increase their body weight to the same degree as the female, i.e., about 100 times. Male ixodid ticks feed for 3–5 days, during which time their weight more or less doubles and after which they will ingest further blood only if the nutrients are exhausted while they are searching for or waiting for a female. They may remain on the host, sometimes seeking a fresh host, for several weeks or months.

Attachment

The attachment of ticks to the host is interesting both from the point of view of the physiological adaptations to this role and from its significance for the health of the host which is of extreme economic importance, the cost of tick and tick-borne disease control being measured in thousands of millions of dollars per year.

The initial lesion is formed by the cutting digits of the chelicerae which in some species may be aided by lytic components of saliva. The hypostome enters the wound and becomes embedded by the recurved teeth which are mainly found on the ventral surface (Fig. 1).

In most ixodid ticks, insertion is accompanied by a flow of attachment cement which enters the wound and bathes the hypostome and chelicerae, apparently hardening almost instantaneously, and which results in a formation characteristic of the tick species or genus involved. The cement casting usually consists of a core wedged into the skin lesion and a spread cone encasing the hypostome and chelicerae which provides a seal on the skin of the host. The cement appears to be basically proteinaceous and, interestingly, contains several

immunogenic proteins also found in salivary gland extracts. The physical nature of the cement prevents these proteins from having antigenic activity. When ticks are forcibly removed, cement is still often found on the mouthparts. Argasidae and some prostriate ticks do not form cement.

While the mechanical action of host penetration is confined to minor damage to adjacent tissues, tick salivary components are responsible for a wide range of tissue changes and local or systemic host reactions. It is not always possible to distinguish direct salivary activities from immune or pathological reactions of the host. The saliva has been shown to have a variety of pharmacological effects. The anticoagulant activity was shown as early as 1898–1899 in *I. ricinus* by Sabbatini and has since been found in other ixodid tick species. In argasid ticks, the excretion of fluid into the host during feeding is minimal. The anticoagulant of *R. appendiculatus* has been isolated and purified from the salivary glands of adults. It is a protein with a relative molecular weight of approximately 65,000 that inhibits blood clotting factor Xa and is mainly produced during the period of rapid engorgement from day 4 to day 7 of feeding and is not immunogenic. Small quantities are effective anticoagulants for large volumes of blood at 10 °C and at room temperature, but at 37 °C, the anticoagulant activity is removed in less than 1 h possibly due to metabolizing activities of bovine or rabbit blood. This may be an indication that the anticoagulant is only active directly at the tick bite site and is possibly a precaution to prevent continuing activities within the tick itself. Tick salivary gland extracts also have effects on vasodilation, vascular permeability, and cytolytic activities.

In both ixodid and argasid ticks, the elimination of excess water and ions is a vital function during the uptake of the more or less exclusively fluid nutrients (Excretory System). Two different strategies are involved in extracting these from the hemolymph. In argasid ticks, coxal fluid secretion starts near the end of or immediately after engorgement. In ixodid ticks, the salivary glands remove the excess fluid from the hemolymph while the tick is still attached to the host, thereby concentrating the blood meal immediately and

allowing a larger volume of blood to be taken up. When this process has been completed, it is a major endeavor of all ticks to prevent any further loss of fluid until the next blood meal.

Some tick species do not form clearly distinguishable hemorrhagic feeding pools at the tick bite site, although there is a distinct area of affected tissue surrounding the tick mouthparts. The fast-feeding argasid adults cause a hemorrhagic pool to develop soon after attachment. The cavity formed beneath the mouthparts of some ixodid ticks may to some extent be a result of host reactions and may not be essential to tick feeding.

Whole blood forms an essential part of the tick's diet. Ixodid ticks can also successfully ingest other tissues practically devoid of red blood cells. *Amblyomma variegatum* nymphs feeding in an in vitro system achieved 24 % higher engorged weights when they fed on heparinized whole blood than when they fed on defibrinated blood from the same bovine donor.

Feeding stimuli are better known from argasid ticks than from ixodids due to the possibility of in vitro feeding which is less successful in ixodids. *Argas* spp. and *Ornithodoros* spp. respond to reduced ► [glutathione](#), nucleotides, and amino acids but in most cases only if at least 1 mg glucose/ml is also present in the medium. There appear to be separate chemoreceptors on the mouthparts, one specific for glutathione and nucleotides and the other for amino acids.

In ixodid ticks, the addition of ATP or glutathione to the medium enhanced the attachment process of ticks partially fed in vitro. Recently, carbon dioxide which is known to be an attractant for ticks (Host Finding) and to have a strong effect on the water balance has also been shown to be a phagostimulant for *R. appendiculatus* and *Amblyomma variegatum*. Using a 5 % CO₂ atmosphere, the larvae and nymphs of *A. variegatum* can be induced to fully engorge in an in vitro system in the total absence of a host animal, achieving engorged weights comparable to those achieved on mammalian hosts and with a high molting rate. *R. appendiculatus* larvae, nymphs, and females can be fed in an artificial system when the CO₂ concentration is 7 %. In this system,

female *A. variegatum* feed more successfully if ATP is added to the whole blood medium upon which they feed.

Digestion

Host tissues, mainly in fluid form, are sucked in by a pharyngeal pump mechanism and pass through the esophagus into the midgut where digestion takes place. In ticks this is a slow intracellular process, in contrast to hematophagous insects where protein digestion basically takes place in the lumen of the intestine. As blood enters the midgut it passes into the large central chamber, from where it is further distributed into the diverticulae by peristaltic movement.

During the first phase of feeding in ixodid ticks, the growth phase, the tick ingests only small quantities of blood, while organs undergo growth and development. This period lasts for about 4–6 days in most species, with almost no blood uptake during the first 12–24 h of preparatory feeding behavior. During the growth phase, blood is taken up by phago- and ► [pinocytosis](#) into the type I digestive cells which are predominant at this time; this is followed by a rapid breakdown of their components. The mobilized nutrients are used to build the cuticle for the enormous expansion during the following phase, as well as for the preparation of intense metabolism during and after feeding. During the second or expansion phase, the major part of the blood meal is ingested by the tick within a period of usually not more than 1–2 days. At this stage the main component appears to be whole blood, while in the earlier stage a large proportion of inflammatory cellular components is contained in the ingested tissues. As the first large part of hemolyzed blood enters the midgut, type II digestive cells become abundant. These cells take up hemoglobin and other proteins by pinocytosis. No signs of phagocytosis have been observed in this cell type. During the expansion phase, the idiosoma of larval, nymphal, and female ixodids shows the characteristic enormous distension which is due to cuticular extension.

Whereas feeding and digestion in ixodid ticks are not separated but merge, digestion in argasid ticks starts after the tick has dropped off its host.

During the first phase, the blood meal is concentrated in the gut lumen with little digestion, while hemolysis of red blood cells begins. This is followed by a second phase of intensive intracellular digestion by the digestive cells. The third phase is characterized by a slow rate of digestion and low metabolic activity of the starving tick while it is waiting for its next blood meal which, in extreme cases, can be delayed for many years.

Hemolysis, i.e., the rupturing of the red blood cell membranes and the release of hemoglobin, has been investigated in *Ornithodoros savignyi* and has been shown to take place gradually as the red blood cell membranes became increasingly fragile. In this tick species, hemolysis was more rapid in males than in females. In ixodid ticks, hemolysis appears to be a more abrupt process, taking place soon after ingestion of blood and leaving no trace of cell membranes in the midgut blood mass. The saliva of *R. appendiculatus* females fed for 4 days was found not to have any hemolytic effect.

Excretory System

The engorged weight of an ixodid tick can correspond to 50–200 times the unfed weight, while there is less weight increase in feeding argasid ticks. The blood is concentrated two to three times during uptake and the volume of the blood in the engorged tick may be only 20 % of the total volume of blood imbibed. Some ticks, particularly members of the genus *Dermacentor*, excrete large amounts of undigested blood through the anus during feeding, i.e., while they are still on the host animal.

In all ticks, the task of removing excess hyposmotic fluid rapidly during or immediately following the blood meal is vital for osmoregulation and is a major excretory effort. In the two main tick families, fluid excretion is achieved by two entirely different mechanisms.

Argasid ticks remove fluid during the final period of engorgement and/or after they have left the host. They can be observed to exude large volumes of a clear fluid from a pore on the first coxal joint. The fluid is secreted from the coxal organ, a tubular osmoregulatory apparatus ending distally in a filtration membrane. This is assumed

to form an ultrafiltrate of hemolymph, which itself receives fluids and ions from the midgut while the blood meal is being concentrated. Further regulation of the fluid balance is carried out in the coxal tubule which leads the final excretory product to the coxal orifice by which it leaves the tick; this mechanism is suited to the fast feeding habits of most argasid ticks which remain attached for a few minutes to 2 h. Argasid ticks appear to inject negligible saliva into the host.

In ixodid ticks, which usually feed for several days or even weeks, removal of hyposmotic fluids is achieved by means of the salivary glands. The salivary gland is a paired acinar organ with a complex of various cells, of which a major portion is granular. Of the three acinus types found in female ixodid ticks, type I and type III acini have been suggested as sites of water secretion (Fig. 9a). There is more evidence available that cells in type III acini are mainly responsible. These cells undergo striking morphological changes during the course of feeding, including the appearance of a cell type designated the “water cell.” Type II and III acini play a significant role as the sites of proliferation of the infective stages of *Theileria* spp. and *Babesia* spp. which are transmitted with the saliva. This may be a further indication of the major excretory function of these two types of acini.

None of the cells found in the acini have been conclusively attributed with specific functions related to the known activities of the salivary gland or the saliva. These include the production of attachment cement and various pharmacologically active components, some of which are shown in Table 3.

In ixodid ticks, the final phase of feeding involves, in particular, a rapid concentration of blood nutrients, during which the hemolymph is loaded with the resulting excess fluid; this excess fluid is then removed by the salivary gland and injected into the host. Feeding is a rhythmic succession of salivation and food uptake. Interfering with salivary gland function or control and hence osmoregulation, such as by applying organophosphate acaricides, results in an inability to remove excess fluid, leading to a disruptive increase in hemolymph volume. During feeding, some ixodid

tick species excrete large amounts of undigested or partially digested blood. Particularly profuse excretion occurs in the genus *Dermacentor* where fecal water loss can be up to 25 % of the total elimination of water. In other species fecal loss may be negligible, but the volume of saliva injected into the host can be as great as, or greater than, the total volume of the engorged larva, nymph, or female.

As in other arachnids, ticks conclude nitrogen metabolism with the production of guanine rather than uric acid. In ticks, nitrogenous excretion is largely separate from ion and water regulation. The guanine content of excreta is very high, and it is eliminated in almost solid form, thus preserving water reserves in the starving tick. Excretion takes place in the Malpighian tubules, a pair of blind-ending slender tubules which form several loops in the body cavity and open into the rectal sac where there may be mixing of Malpighian excreta with feces before elimination of both forms through the anus. In engorged female ixodid ticks, the Malpighian tubules are grossly distended and visible through the integument as wide yellowish lines which increasingly fill the body cavity, since the tick eliminates only a very limited amount of metabolic waste before dying. Ticks kept at constant temperatures under laboratory conditions appear to defecate less frequently,

but in greater quantity at a time, than ticks exposed to natural diurnal temperature rhythms. This may be a factor contributing to the longer survival of many ticks kept under natural temperature regimes.

Nervous System

In ticks, there is a very close association between the nervous and the circulatory systems. This is demonstrated by the enclosure of the entire central nervous system within a perineural sinus of the circulatory system; this receives a dorsal aortic vessel and gives rise to vessels enclosing the major nerve trunks.

No part of the central nervous system is located within the gnathosoma of the tick, which therefore does not correspond to the head in the generalized arthropod. The brain is located centrally at the level of the second coxa. Ticks can be killed quickly by crushing this region with a hard object (ticks are very resilient: a practical method of destruction is with hot water). The central idiosomal position of the central nervous system makes it poorly accessible for direct investigations.

The tick central nervous system is more condensed than in other ► [Chelicerata](#). It is a synganglion, formed by the fusion of the brain ganglia and the abdominal nerve cord into a single

mass. The nerve trunks arising from the ganglia are formed by axons of both receptor and motor cells. As in other acari, the synganglion is divided into two parts by the esophagus. Cranially, the esophagus lies beneath the synganglion, then crosses obliquely through the synganglion in a ventrodorsal direction to lie dorsally on the posterior portion before joining the midgut. The cranial, pre-esophageal part of the synganglion consists of the protocerebrum, the optic lobes, the cheliceral and pedipalpal ganglia, and the stomodeal pons or bridge.

All ticks examined have been found to possess well-developed photoreceptors, even the “eyeless” ticks (*Aponomma*, *Ixodes*, *Haemaphysalis*). They also have optic nerves and optic ganglia in the brain. A set of paired nerves extends from the optic lobes, a second set of paired nerves serves the chelicerae, and a third innervates the pedipalps. The unpaired stomodeal or pharyngeal nerve innervates the pharynx.

The postesophageal part of the synganglion gives rise to four pairs of pedal ganglia serving the four pairs of legs in the adult tick. Fine “sympathetic” nerves connect all four pedal nerve trunks laterally on each side of the synganglion. Several pairs of opisthosomal nerves innervate the viscera. The ventral lobes of the pedal ganglia of leg 1 contain discrete areas of highly differentiated neuropile which are thought to receive olfactory fibers from pedal nerve 1 and have been called olfactory lobes.

Associative centers are represented by several bilaterally symmetrical glomerular structures. Anterodorsal, posterodorsal, and ventral glomeruli in the pre-esophageal part are connected by nerve fiber trunks. A complex of nerve fibers and trunks in the postesophageal part of the synganglion forms a five-level commissure-connective system.

The synganglion and all peripheral nerves are covered by a connective tissue sheath, the neurilemma, below which there is a relatively thin layer of glial cells, the perineurium. Beneath these layers, subperineural glial cells are located on both sides of a cortex layer of nerve cell bodies surrounding the central fibrous neuropile, which constitutes the greater part of the synganglion mass.

There is some direct and indirect (effects of acaricidal activity) evidence that acetylcholine and catecholamines (dopamine, noradrenaline, norepinephrine) play a role as neurotransmitters in ticks. However, the role of these substances, which are known to act as neurotransmitters in other animal groups, must remain speculative until further evidence has been provided.

Host Finding

The various tick species show very different types of host-finding and feeding behavior patterns. For example, they may find their hosts by active hunting or by ambushing behavior, they may use one host for their whole life cycle or depend on the acquisition of two or more hosts, or they may be specialized on a specific host type or show little specificity for particular animal groups. In one-host ticks, host-seeking takes place once during the whole life cycle. The risks involved are thus reduced in comparison with two-, three-, or multiple-host ticks where there are correspondingly more critical periods for each individual. Ticks which can complete their whole life cycle within one limited environment (e.g., nest, burrow, cave) may nonetheless be exposed to long periods of starvation during migration and other seasonal or irregular absences of the host. This risk is reflected in the ability of starving in soft ticks to survive for periods of up to 14 years. Judging by the large number of offspring and the long periods of starvation to which ticks can be exposed, the chances of finding a new host appear to be fairly poor.

Host-finding of most ticks can be divided into phases such as ► [habitat selection](#), host recognition at a distance, changeover to the host, enduring contact with the host, exploration (selection of a feeding site), and the sequence of behavior patterns related to the feeding process such as piercing (insertion of the mouthparts), attachment of the mouthparts, secretion of salivary gland contents, ingestion, detachment of the mouthparts, and leaving the host.

Microhabitat Selection

Following hatching or molting and a period of quiescence, ► [host finding](#) is aided by orientation

responses, which in ixodid ticks lead to a favorable distribution on the vegetation or other sites. In argasid ticks, orientation may depend on the presence of suitable hosts and may be more marked at night, as in the case of *Argas persicus* or *A. reflexus* in which the adults and nymphs feed on roosting avian hosts, remaining hidden during the day.

Much of the behavior of ticks seems to be dedicated to selecting optimal resting sites. Host-finding behavior is often only displayed when the environmental and physiological conditions support their survival. During host seeking, ticks normally select microhabitats with good opportunities to encounter a host. Many species ascend vegetation to heights favorable for contacts with the particular hosts. Also, the time of day has an effect on the microhabitat selection. For example, the larvae of the cattle tick *Boophilus microplus* ascend vegetation in the early morning and again in the evening. The microhabitat selection is achieved by responses to environmental cues such as gravity, light, and humidity.

Host-Finding Strategies

Ticks respond to hosts at a distance with various behavior patterns, depending on their host-finding strategy: Many ticks, in particular, certain *Hyalomma*, *Amblyomma*, *Ornithodoros*, and *Dermacentor* spp., seek their hosts by hunting; they move actively in the direction in which the host is seen or sensed. Due to their limited mobility, more abundant among ticks is the ambushing strategy, in which the parasites await the hosts in their selected microhabitats in the vegetation. They respond to host cues with questing behavior, i.e., an erect posture, in which the first pair of legs is waved in the direction of the host stimuli. The larvae of *Boophilus* spp., and probably the larvae of most ixodid ticks, show marked ambushing behavior. The larvae of *B. microplus* ascend the vegetation early in the morning and again in the evening to a height favorable for attaching to cattle passing close by. In other species, similar ambushes are prepared at heights appropriate to the preferred host species.

Host Recognition

The approach of a suitable host is heralded by several stimuli such as volatile host emanations,

vibrations, visual cues, radiant heat, and touch. These cues are taken up by sense organs concentrated at the anterior end of the tick which indicate proximity of the host. There may be no response from quiescent ticks. Sense organs suspected to be involved in the host location and feeding behavior of ixodid ticks have so far been located at three main sites: on the tarsi of the first pair of legs, on the mouthparts, and on the scutum. They include olfactory, gustatory, mechano-, photo- and thermoreceptors, and probably humidity receptors. The dorsal surface of the tarsi on leg I of ticks has a unique set of sensory structures which include Haller's organ complex housing some of the tick's olfactory chemoreceptors. Other sensory organs on the tarsi are gustatory, mechano-, and thermoreceptors. The involvement of Haller's organ in host perception is evident from the "questing" posture of an alert tick, which lifts its first pair of legs and waves them while taking up a position favorable for dropping or crawling onto the host. In this function, the legs and the olfactory receptors correspond to the antennae of insects.

Volatile host emanations are the most important cues in tick host finding. Most tick species are attracted by sources of carbon dioxide which can function as an "artificial host" and be used to demonstrate how active a tick is in finding a host. Activity ranges between hunting and ambushing behavior. Hunters are attracted to the carbon dioxide-emitting source and can be trapped with this gas, and ambushers respond sensitively with questing behavior. *Amblyomma americanum* is actively attracted by a carbon dioxide source from a distance of 21 m and carbon dioxide appears to also act as a phagostimulant. The more specific a tick species is in its choice of host, the more likely it is to require additional highly specific chemical stimuli to alert and attract it to the host. However, little is known on how different host specificities are encoded in the odors. The characteristics of tick olfactory sensilla suggest that they use very different compounds of the odors for host identification. This may be concluded in particular from data on the sensilla of tarsus I (including those of Haller's organ) of *A. variegatum*. Gas chromatography-coupled electrophysiology recordings using different

vertebrate odors allowed the identification of specific receptors for lactone (two receptor types), methylsalicylate, carbon dioxide (two types), sulfide (two types), benzaldehyde, 2-hydroxybenzaldehyde, aliphatic aldehydes, 2,6-dichlorophenol, nitrophenol, pentanoic acid, 2-methylpropanoic acid, butanoic acid, ► [ammonia](#) (two types), and 3-pentanone.

Also, the behavior responses of ticks indicate that they may react to different components of host odor and that they may discriminate the odors of different host types. For example, the larvae of the bovine-specific *B. microplus* responded sensitively with questing behavior to skin surface odors of cattle, but only weakly or not at all to those of humans, pig, mouse, and deer, whereas the larvae of the generalist *I. ricinus* responded similarly to the different odors. Blends of synthetic odor compounds stimulated questing in both species. The stimulating activity of a blend of 37 compounds was achieved by a combination of only 7 of the compounds which as single substances were without effect (benzoic acid, 2-ethylhexanoic acid, hexanoic acid, 2-nitrophenol, 1-octen-3-ol, pentanoic acid, and pyruvate). Under these conditions, *B. microplus* achieved its specificity for bovine odors by responding more to the bovine-specific compounds 1-octen-3-ol and 2-nitrophenol, whereas *I. ricinus* reacted to each of the seven compounds with similar intensity. Obviously, the response of ticks to odor is stimulated by a combination of different compounds, rather than by particular individual compounds, and also specific hosts may be recognized via the interplay of different odor compounds.

A special attraction to hosts occurs in certain species of *Amblyomma*. Females are attracted to the ungulate hosts by attraction/aggregation-attachment pheromones which are emitted by feeding males on the hosts. The major chemical components in the pheromone are ortho-nitrophenol, methyl salicylate, and pelargonic acid.

The ocelli of some tick species are sufficiently developed to play a significant role not only in perception of light and darkness but also in perception of the host itself. Paired ocelli are found at the edge of the scutum at about the level of the second pair of legs. In argasid ticks they are

smaller and found in folds at the sides of the idiosoma. In *Omithodoros savignyi*, there are two pairs of ocelli. Even “eyeless” ixodid ticks (of the genera *Aponomma*, *Haemaphysalis*, *Ixodes*) have been found to have well-developed photoreceptors and optic ganglia in the brain. In ticks with ocelli, there is a lens, a hemispherical, transparent, flat or convex cuticular thickening, underneath which a small group of photoreceptors or optic cells are situated. An optic nerve extending from this location leads to the optical center of the synganglion. This has been studied in *A. americanum* and in *Hyalomma asiaticum*. Vision in some species of *Hyalomma* and *O. savignyi* is thought to enable these ticks to actively pursue their hosts over long distances.

Also, vibrations which stimulate host-finding responses in many ticks may signal some host specificity. Sounds in the range of 3,000–8,000 Hz, as produced by swallows, stimulate hunting in *O. concanensis*, and airborne vibrations in the range of 80–800 Hz, as elicited by grazing cattle, activate *B. microplus* larvae.

Radiant heat as another host cue may be effective over certain distances and offers directional information. Hunting species are attracted to heat sources and ambushers respond to heat with questing behavior.

Changeover to the Host

Alert ticks cling to any moving substrate touching them. Particular host cues do not seem to be necessary for the changeover to a host. However, on the host's surface, gustatory and olfactory cues seem to decide whether the parasites will remain on the host, and they guide the parasites to particular feeding sites. Some species prefer feeding sites where they are out of reach of the attacks by the grooming behavior of the hosts. Little is known on how the feeding sites are found. On artificial substrates, ticks orientate towards certain host skin extracts, but the chemical nature of the directing cues still has to be analyzed.

Feeding Site Selection

Once on the host animal, many tick species will not probe until they have arrived at the preferred feeding site and are out of reach of grooming by

the host. On the few occasions that male ticks climb onto unsuitable hosts, they may probe immediately. Female ticks appear to avoid or reject inappropriate hosts more than males, but may engorge in exceptional cases. The carnivore tick *Haemaphysalis leachi* may engorge on bovines and lay viable eggs under conditions where dogs and cattle are kept in close contact.

In certain *Amblyomma* spp., an aggregation of the parasites at specific feeding sites is supported by the male-emitted attraction/aggregation-attachment pheromones which attract conspecific males, females, and nymphae. In the majority of the hard ticks studied so far, feeding females produce an attractant sex pheromone containing 2,6-dichlorophenol which attracts males to the feeding site.

Drop-Off

The drop-off periodicity and its correlation with the distribution and habits of possible hosts for the next feeding are particularly important for ectoparasites of host animals that do not exhibit nesting behavior. In some tick species, it has been observed that drop-off times are regulated by a circadian rhythm related to the daily light cycle. There may also be a host-induced rhythm. Darkness plays the principal role in setting the phase of the rhythm. This may be combined with changes in temperature, such as those during movement from the shade of trees to light or vice versa, or from the stable to sunshine. In some ixodid ticks, such as *Boophilus* spp. females or *A. variegatum* nymphs, the sudden exposure of bovine hosts to increased light can trigger a rapid drop-off of engorged ticks. Such an effect is likely to cause the next tick stage to be found close to host-resting places. In tick species where the next stage has different host preferences, more complicated strategies may arise to ensure the availability of the next host candidates. After dropping off, the engorged larvae of some ixodid tick species tend to move downward, whereas in other species there may be a tendency toward upward movement. These movements may reflect the nesting or nonnesting habits of the resultant nymphal tick's preferred next host.

Artificial Feeding Methods

Much information on the host-recognition phases of the ticks on the host's surface comes from studies dealing with the development of artificial feeding methods. The feeding sequence consists of behavior patterns such as piercing the skin with the cheliceral digits, anchoring with the hypostome-chelicerae complex to the attachment site (possibly with cement material), salivary gland secretion, uptake of host body fluids, withdrawal of the mouthparts, and leaving the host. Important cues for successful feeding on artificial membranes are unknown chemical compounds of skin extracts, heat, humidity, carbon dioxide, and mechanical properties of the membranes. Reduced glutathione, nucleotides, and amino acids seem to function as phagostimulants. Feeding in in vitro systems now provides the means to investigate tick-pathogen relationships without the complication of feeding ticks on acutely infected hosts.

Chromosomes

As in many other arthropod taxa, several groups of tick species are not sufficiently defined for a reliable differentiation and classification of species and subspecies. The scanning electron microscope has provided a tool to support morphological differentiation, but few investigations have included a biological background to validate the authenticity of species based on minor morphological differences and/or on host preferences. This is not required where the morphology is unique and is nearly impossible in the ectoparasites of rare and elusive host animals.

Cross-breeding trials have been used to substantiate the results of morphological investigations. Thus *Argas persicus*, *A. arboreum*, and *A. walkerae* have been confirmed as separate species. The males of two ixodid species, *Rhipicephalus appendiculatus* and *R. pulchellus*, can induce females of the other species to complete feeding although mating does not take place. In this way, some *R. appendiculatus* females can produce viable eggs and larvae, which can normally only take place after being triggered by conspecific mating. There is no parthenogenetic development in *R. pulchellus*. The phylogenetic

relationship appears to be close enough for common pheromones to be present even though appropriate behavioral patterns are lacking. Intersubspecific hybrid formation between *R. evertsi evertsi* and *R. e. mimeticus* has confirmed the separation at subspecies level rather than at species level. When *Boophilus annulatus* and *B. microplus* are mated, sterile hybrid males and fertile hybrid females are produced. The female hybrids produce sterile males when backcrossed with males of the male parent species. Theoretically, sterile hybrid *Boophilus* ticks could be used to eradicate low-level *Boophilus* populations.

Studies on the cytogenetics of tick species may eventually provide a useful means of investigating phylogenetic relationships and may also provide a taxonomic tool for studying living tick specimens. The ► [chromosomes](#) of several tick species have been described. Most species are diploid. The diploid chromosome number in ticks ranges from 12 to 36, the whole range being present in the genus *Omithodoros*, where *O. guernei* has 12 and *O. alactagalis* has 34. Both species of *Otobius* (*O. megnini* and *O. lagophilus*) possess 20 chromosomes. In *Argas* most investigated species have 26 chromosomes (with 24 autosomes plus two sex chromosomes), exceptions being *A. vespertilionis* (20) and *A. brumpti*, with 24.

In the ixodid bisexual species which have been studied, there is a range of 17–28 chromosomes. The most common number of chromosomes and sex-determining mechanism found in metastriate ticks is 20 + XX in females and 20 + X in males. This combination is found in 11 species of *Rhipicephalus*, 12 species of *Hyalomma*, 3 species of *Boophilus*, and in some species of *Amblyomma*. The range in *Amblyomma* is from 19 to 22, in *Aponomma* from 17 to 21, in *Dermacentor* from 20 to 22, and in the bisexual species of *Haemaphysalis* from 19 to 22. In the parthenogenetic races of *Haemaphysalis longicornis*, there is a triploid chromosome set with 30–35 chromosomes. The prostriate genus *Ixodes* has a chromosome range of 23–28, with 23 in *I. holocyclus*, 24 in *I. cornuatus* and *I. tasmani*, and 28 in others.

The male usually has one chromosome less than the female, except in *Ixodes*. With six

exceptions, all members of the Metastrata have XO:XX male: female sex chromosome systems. Four species possess an XY:XX system, as do the Prostrata with the exception of *I. holocyclus*, which has XO: XX. All argasid species described have XY:XX chromosome systems. Two *Amblyomma* species have multiple sex chromosomes, with two different X-chromosomes in males and females. Chromosome polyploidy is suspected in some ixodid species, too. In general parthenogenesis is rare in ticks. If it does occur, it is accomplished by thelotoky; in such cases, all the progeny are female and polyploidy is frequently associated with this type of reproduction. An obligate parthenogenetic tick is *Amblyomma rohndatum*; in *Haemaphysalis longicornis*, this phenomenon occurs more often than in *Dermacentor variabilis*. The morphology of the chromosomes is species-specific. An X-chromosome is invariably longer than the autosomes (often three to four times as long) and represents the isobrachial type (= metacentric), while the Y-chromosome is usually heterobrachial (= submetacentric). The autosomes are mostly acrocentric.

Introduction

Human populations are becoming increasingly vulnerable to infection by tick-borne pathogens (► [Arboviruses](#), ► [Babesia](#), ► [Theileria](#), ► [Bacteria](#)). These infections are more intense and diverse now than they appeared to be during the mid-1900s. Our recent experience with ► [Lyme disease](#), human babesiosis, and human ► [ehrlichiosis](#) illustrates this pattern of emergent tick-borne infection. This trend is driven by a proliferation of vector ► [ticks](#) in many parts of the world and widespread human encroachment into forested sites. The purpose of this review, therefore, is to identify the environmental determinants of tick-borne disease. In particular, we shall review concepts concerning the diverse modes of perpetuation of tick-borne agents and identify conditions leading toward human infection. Although Lyme disease will be emphasized, this review will include other tick-borne pathogens that share similar ecological features.

Biology of Ticks

► [Ticks](#) are arthropods, as are insects, but are classified with the ► [mites](#) and ► [spiders](#). They may readily be distinguished from insects by their

characteristic flat, unsegmented bodies, absence of antennae and four pairs of legs in the nymphal and adult stages. All ticks share various structural features employed for finding and feeding on vertebrate hosts. Their mouthparts include retractable ► [chelicerae](#) that penetrate the vertebrate skin and a multispined ► [hypostome](#) that affixes the feeding tick to its host. Olfactory setae, located on the anterior ends of their legs, serve to detect the presence of such animals. Hooklike structures at the ends of their legs enable ticks to attain contact with passing hosts. These features facilitate the parasitic mode of life.

The two major taxa of ticks, the ► [Argasidae](#) (soft ticks) and the ► [Ixodidae](#) (hard ticks), differ radically in structure, life history, and pathogen associations. The ► [cuticle](#) encasing the bodies of soft ticks is leathery while that of hard ticks is rigid. It becomes elastic, however, as a hard tick fills with blood. Soft ticks are endemic to arid regions and are closely associated with the nests or burrows of birds or rodents. Such ticks feed frequently during each trophic stage and become attached to their hosts only briefly, generally for no more than an hour. Each of these feeding episodes provides a tick-borne pathogen with another opportunity to infect susceptible hosts. Hard ticks, in contrast, feed for several days or more and do so only three times during their entire lifespan: once during each of the three trophic stages. Although pathogens of hard ticks have fewer transmission opportunities than do soft ticks, they maintain a diverse array of viral, bacterial, protozoan, and metazoan pathogens. Soft ticks in contrast, transmit only ► [relapsing fever](#) spirochetes, a complex of pathogens that is restricted to a few particularly arid sites. The following discussion, therefore, will focus exclusively on hard ticks and their associated pathogens.

Ticks require vertebrate blood to grow and to reproduce. Molting follows each feeding episode by a subadult tick. The life cycle culminates after adult ticks feed and the female deposits a batch of eggs. Ticks ingest enormous quantities of blood, hundreds of times their prior weight. A complex series of physiological events within the vertebrate host and vector tick facilitates this feeding

process. The mouthparts of the tick penetrate the skin and secrete a cement-like substance that affixes it to the host. During blood feeding, antihemostatic and anti-inflammatory components of the saliva are secreted into the host to prevent platelet activation and suppress the immune response of the host. The tick ingests a mixture of blood and tissue fluids from the skin of its host in a manner that is poorly understood. The exoskeleton then becomes plastic and unfolds, accordion-like, to accommodate the final phase of blood feeding. Vast quantities of blood are ingested during the final 24 h of feeding. The bloated tick then withdraws its feeding apparatus and proceeds to digest its meal of blood. Replete ticks either molt to the next developmental stage, if subadult, or, if adult, produce a clutch of eggs. Death follows ► [oviposition](#).

Ticks may survive for months or even years between feeding episodes. They remain motionless in a dormant state until ► [environmental conditions](#) permit them to resume activity. Day-length and temperature serve as seasonal cues to initiate or suppress questing activity. During their questing season, ticks generally ambush their hosts. They leave their sheltered habitats, ascend on vegetation to a height commensurate with the body-form of their host, and wait for any passing object. Those ticks that hunt more aggressively may actively pursue their hosts. Such ticks will move great distances in response to carbon dioxide and other host-related stimuli to locate suitable hosts.

Perpetuation of Infection

Virtually all tick-borne microbes that cause human disease are zoonotic, in that they perpetuate mainly as parasites of certain nonhuman reservoirs. Each human infection, therefore, constitutes a diversion that reduces the force of transmission. Ticks that narrowly focus their feeding on a particular reservoir population most effectively amplify the natural cycle of transmission of the pathogen. Vector ticks that feed most frequently on people would seem to contribute least to the enzootic cycle of transmission because their host-range is broad. Infections tend to

perpetuate most readily in those ticks that seem innocuous because they rarely come in contact with “dead-end” human hosts. This paradox, that is common to all ► [zoonoses](#), is resolved in sites where species diversity is limited. In such sites, vectors that fail to discriminate between hosts may sustain enzootic transmission while allowing for episodes of human infection to occur.

Contribution of Vector Ticks

The intensity of transmission of a tick-borne pathogen is determined, in part, by a series of vector-related physiological and ecological variables. The salient properties of the tick population include (1) competence, (2) abundance, (3) site-fidelity, (4) longevity, (5) seasonality, and (6) narrowness of host range. The term “► [Vector Capacity](#),” which is based on a comprehensive synthesis of these six entomological properties, describes the number of new infections derived from each originally infected reservoir animal per unit of time. The relative contribution of each of these variables to the force of transmission of a tick-borne pathogen remains poorly defined. These variables will be discussed, in turn, in the discussion that follows.

Vector competence describes the physiological suitability of a particular kind of arthropod as host for a microbe. This parameter is measured in the laboratory and estimates the proportion of ticks that acquire, maintain, and transmit a pathogen between vertebrate hosts. Vector ticks, therefore, must be able to ingest sufficient infectious organisms for the pathogen to become established, must maintain infection transtadially through the relevant molt and must deliver a sufficiently large inoculum to infect a particular vertebrate host. In addition to this horizontal mode of transmission, certain pathogens are maintained vertically, by inherited infection. The various babesial infections of cattle, for example, illustrate this pattern of transmission by inheritance, while the rodent babesias rely exclusively on horizontal passage between the larval and nymphal stages of development. Although Lyme disease spirochetes (► [Borrelia burgdorferi](#)) mainly perpetuate in a

similarly horizontal cycle, occasional episodes of inherited infection seem to occur. Transmission by cofeeding, i.e., direct passage of a pathogen from the mouthparts of an infected tick to those of a noninfected tick, has been demonstrated in laboratory experiments but not in the field. These cycles defy generality.

Vector abundance constitutes an important variable in the force of microbial transmission. When vector ticks are sparsely distributed, individual reservoir hosts may not sustain the requisite number of vector contacts; only a few reservoir animals would acquire and subsequently pass-on the pathogen. They might only rarely acquire infection or acquire infection so late in the transmission season that they would infect few ticks. Intensity of transmission correlates directly with vector density relative to the density of reservoir hosts.

Because the environmental requirements of ticks tend to be highly specific, their distribution is discontinuous. Vector ticks, therefore, must be sessile enough to preclude dispersal from their point of origin. Although ticks generally remain close to their point of origin, some may migrate several hundred meters in response to such host-associated stimuli as carbon dioxide. Those that attach to vagile hosts, such as birds, may readily be carried away from a permissive habitat and be lost to the transmission cycle. In this manner, tick-borne infections simulate the classical Russian concept of the "nidality of disease."

The proportion of the tick population that survives long enough to become infectious also influences the force of transmission. Incidence of infection in the reservoir population, therefore, depends directly on interstadial survival of the vector tick. Indeed, the vast majority of ticks that feed as larvae fail to feed once again as nymphs. In northeastern USA, for example, 3.5 times as many larval as nymphal deer ticks (*Ixodes dammini*) attach to white-footed mice (*Peromyscus leucopus*). Almost a third of these ticks appear to survive to feed again. In addition to longevity, however, this estimate of survival assumes that each relevant developmental stage of the tick responds similarly to the array of available hosts. Transstadial survival has not been estimated

directly, and the magnitude of its contribution to the force of transmission remains unknown.

The seasonality of feeding activity of the vector tick relative to the density of the reservoir population may also affect transmission. In the case of the American vector of the agent of Lyme disease, seasonality is highly punctuated. The nymphal stage of the tick feeds, each season, before the younger larval stage. This inverted pattern of feeding serves to intensify transmission of pathogens because the reservoir population receives its infectious inocula before the larval recipient stage of the tick commences feeding. Because European wood ticks (*Ixodes ricinus*) lack such a precisely punctuated developmental cycle, the cycle in Europe seems less efficient than in eastern North America. The requirement for precision would be exacerbated in the event that reservoir hosts remain infectious only for a brief period of time. The pathogen must then become available to the vector population precisely when the appropriate stage of the vector quests for hosts. Seasonal events may profoundly affect transmission.

Narrowness of host range of the vector tick powerfully affects transmission because hard ticks feed only three times per generation. At least two of these feeding episodes must be directed toward the population of reservoir animals that enables vectors to successfully acquire and ultimately transmit the pathogen. For example, only larval and nymphal stages of the deer tick feed on rodent reservoirs, while adults parasitize larger noncompetent hosts such as deer. Diversion of either of the subadult stages to noncompetent hosts, therefore, negates transmission for the other feeding episode.

Contribution of Reservoir Hosts

Although vector ticks may acquire infection from an array of hosts existing in nature, only one generally serves as the main reservoir of the pathogen. "Reservoir capacity" expresses the relative number of infected ticks derived from each host species. An effective reservoir host must be (1) competent for the pathogen, (2) sufficiently

abundant, (3) parasitized by numerous vector ticks, (4) parasitized by at least two developmental stages of the vector tick, and (5) continuously resident in the enzootic site. These biological properties, together, define the capacity of reservoir populations to perpetuate tick-borne pathogens.

Reservoir competence is a measure of the physiological ability of a vertebrate host to exchange a pathogen with vector ticks, and generally is analyzed experimentally in the laboratory. A competent reservoir must readily acquire infection, sustain its development, and ultimately present the pathogen to the vector. This parameter should be measured over a span of time that corresponds to that of the seasonal activity of the vector tick. For the Lyme disease agent in North America, for example, reservoir hosts must become and remain infectious over the 2 month interval spanning the maximum feeding activity of nymphal and larval deer ticks. The white-footed mouse fulfills this criterion because it attains infectivity within 2 weeks of infection and remains infectious for life. A competent reservoir, therefore, must remain infectious long enough to pass infection to the relevant stage of the tick.

Reservoir hosts should be sufficiently abundant in nature that vector ticks are likely to encounter them before encountering other less suitable but tick-attractive hosts. Although the force of transmission initially increases with reservoir density, greater host density might dilute the vector population such that individual hosts that become infected are unlikely to encounter and infect noninfected ticks. The presence of tick-attractive but pathogen-incompetent hosts would divert vector ticks, a relationship known as "zooprophylaxis." Transmission, therefore, tends to be most intense in ecological island sites where host diversity is restricted and particular reservoir hosts predominate.

A complex set of ecological and physiological properties of reservoir and vector populations determines the frequency of vector–host contact. Effective reservoirs, of course, must occupy the same habitats as do vector ticks. Ticks position themselves on the vegetation at an appropriate

height above the ground, thereby ensuring a degree of host specificity. The stature of particular hosts influences the probability of encountering a tick in nature. In addition, reservoir hosts must forage at a time of day when ticks actively seek hosts. Ticks quest most effectively at night and during the morning and evening hours when the atmosphere is sufficiently humid. Once a questing tick attains host-contact, it must successfully feed without invoking an inflammatory response. Poorly adapted hosts develop an inflammatory response against tick bites after repeated exposure. Such resistant animals feed fewer ticks due to the direct effects of host immunity and irritation induced by tick bites which increases host grooming. The physiological and ecological variables that regulate host–tick contact remain poorly understood.

Reservoir hosts must have sufficient contact with pathogen-acquiring and infecting stages of the tick to perpetuate the pathogen. Entomological inoculation rate (EIR) describes the frequency of vector ticks delivering infection to the reservoir population. This variable depends on the frequency with which pathogen-infective stages of the tick feed on a particular reservoir population and the prevalence of infection in these ticks. To complete transmission, reservoir hosts must be abundantly parasitized by the pathogen-receptive stage of the tick. Reservoir inoculation rate (RIR) describes the number of infections generated in the vector population per unit of time. Together, these variables describe the ability of particular kinds of hosts to receive (EIR) and deliver (RIR) infection to and from the vector population.

Reservoir hosts should remain within the enzootic site throughout the transmission season. Mobile hosts such as birds tend to be ineffective reservoirs because they may readily disperse the pathogen to an inappropriate site that lies outside of the focus of transmission. Although migratory hosts may fail to maintain infection locally, they may passively transport ticks into new permissive sites. In this manner, excessively mobile hosts may reduce the force of transmission of a pathogen locally while accelerating the expansion of its range.

Risk of Infection

The potential for tick-borne pathogens to infect human hosts depends on the questing density of infected ticks and the behavior of human hosts. Herein, we explore the conditions that may favor human infection.

The density of ticks largely correlates with that of their main vertebrate host(s). Definitive hosts, in particular, powerfully affect tick abundance because they comprise the main food source for the reproductive stage of the tick. Successful feeding of the adult stage of the tick results in huge increments of increase: thousands of larvae may result. In contrast, feeding success by subadult ticks merely promotes development. Adult deer ticks, for example, feed mainly on deer and proliferate solely where deer are abundant. This relationship was tested experimentally by depriving deer ticks of access to their cervid hosts. Deer inhabiting an island site were virtually eliminated, which resulted in a diminished tick population. The density of larvae per mouse declined fivefold during the year following the intervention, and that of nymphs somewhat more slowly, extending over several years. This relationship, however, appears to be nonlinear because incremental decreases in deer density may fail to reduce tick densities. Modest reductions in deer abundance may simply cause more ticks to feed on each remaining host. The quantitative relationships between tick and host density have not been defined precisely.

Seasonality in the questing density of ticks may profoundly affect the shape of the epidemic curve representing any pathogens that they transmit. In North America, human Lyme disease infections tend to occur most frequently during July because fewer people engage in risk-promoting activities during May and June, when deer tick densities are greatest. Nymphal densities decline greatly by July and are virtually nonexistent in August. Fewer human infections occur during the fall and winter months, although adult ticks, which quest at that time of year, are far more frequently infected than are nymphal ticks. Few people, however, are exposed and those that enter forested sites then are fully clothed. Then too, adult ticks are more readily discovered before

they can feed long enough for transmission to occur. Risk of human infection is modified by a complex interaction of the stage-specific activity of vector ticks and human behavior.

Pathogen-infected vector ticks may be more abundant in certain sites than in others and infection far more prevalent than in the case of insect-borne disease. The Lyme disease spirochete, for example, infects 20–40 % of deer tick nymphs and 40–70 % of adults in northeastern and northcentral USA but rarely infects ticks south of Maryland. Likewise, human infections cluster in space and time mainly in the upper Midwest and Northeast, but also in several sites in California. Elsewhere, the scattered distribution of human cases suggests that infected ticks may be imported, perhaps carried by south-migrating birds. Enzootic transmission implies that both vector and pathogen populations propagate locally. Larval ticks, for example, would outnumber nymphs where transmission is stable; a preponderance of nymphs would imply that the vector population is sustained by importation from some remote enzootic site. In a stable zoonotic focus, the RIR (prevalence of infection in the reservoir and feeding density of vector ticks on those hosts) would be consistent with the EIR (stage-specific density of infected ticks). Stable transmission requires long-term constancy in the incidence of infection in both vector and reservoir populations.

Outbreaks of tick-borne disease may emerge when people encroach upon previously silent transmission foci. In this manner, focused contacts between reservoir hosts and vector ticks may be altered and redirected toward human hosts. The first outbreak of ► [Rocky Mountain spotted fever](#) erupted, for example, when pioneers cleared land in the Bitterroot Valley of Montana. The result was devastating, nearly preventing this fertile region from developing. ► [Tick-borne encephalitis](#), likewise, became intensely prevalent when forestry workers and trappers relocated into undisturbed tracts of Siberian forest. Human disruption of enzootic cycles serves to produce sporadic outbreaks of tick-borne disease.

Environmental change may promote epidemics of tick-borne disease when particular hosts and ticks become extraordinary abundant.

Reforestation of previously cultivated land in eastern USA has permitted deer to proliferate, often in close proximity to residential communities. Lyme disease emerged as a significant health problem when deer and their associated tick ectoparasites increased in abundance and expanded in distribution. The first outbreak of ► [Crimean-Congo hemorrhagic fever](#) occurred when population densities of hares and *Hyalomma marginatum* vectors exploded after hunting was prohibited and fields were abandoned. Massive outbreaks of human infection followed the resulting proliferation of these apparent reservoir hosts. Any disruption in the balance of vertebrate hosts may support an overabundance of vector ticks.

Example of Lyme Borreliosis

While *Borrelia burgdorferi* is the sole causative agent of human Lyme disease in North America, the etiologic agents in Europe and Asia are more diverse. They include the “genospecies” designated as *B. burgdorferi*, *B. afzelii*, and *B. garinii*. These spirochetal agents of human disease are transmitted by members of the *Ixodes ricinus* complex, including *I. dammini* in eastern North America, *I. pacificus* in western North America, *I. ricinus* in Europe, *I. persulcatus* in eastern Europe and Asia. People become infected mainly via the bites of nymphal ticks, although some infections may be derived from the adult stage of the tick. In certain communities, Lyme disease transmission may be particularly intense. Lyme disease spirochetes may infect as many as 40 % of nymphal ticks and virtually all of the rodents. Human seroprevalence may approach 25 %, and 5 % of residents may become infected each year. Currently, Lyme disease accounts for more than 90 % of all reports of vector-borne disease in the USA.

In northeastern USA, the Lyme disease spirochete perpetuates in a cycle involving vector deer ticks (*I. dammini*) and white-footed mouse reservoir hosts (*Peromyscus leucopus*). White-tailed deer (*Odocoileus virginianus*) are not directly involved in the transmission cycle, but play a vital role in maintaining tick densities because

they serve as the preferred hosts of the adult stage of the vector tick. Although various other vertebrate hosts may inhabit zoonotic sites and come in contact with vector ticks, white-footed mice provide the main source of spirochetal infection to the nymphal stage of the vector tick. These mice serve as effective reservoirs because they are locally abundant in zoonotic sites, are the main hosts for the larval and nymphal stages of the vector, are frequently infected in nature, and readily infect vector ticks. Estimates of reservoir capacity suggest that one white-footed mouse infects as many ticks as do 12 chipmunks or 221 meadow voles. Some kinds of passerine birds may also transmit infection to the vector population. The greater mobility of avian hosts diminishes their contribution to local transmission but ► [aids](#) in dispersing vector ticks and Lyme disease spirochetes to new sites.

The apparent diversity of vector ticks, spirochete variants, and the vertebrate reservoir fauna of western USA renders the ► [epizootiology](#) of these microbes more complex than in the Northeast. Although *I. pacificus* serves as the principle vector to people in this region, relatively few harbor Lyme disease spirochetes. The diversity and abundance of noncompetent hosts in western USA appear to contribute to low infection rates in *I. pacificus*. *I. neotomae*, in contrast, narrowly focuses its feeding on wood rats and kangaroo rats and may effectively maintain Lyme disease spirochetes in an enzootic cycle involving these hosts. Lyme disease spirochetes may perpetuate in this *I. neotomae*-wood rat cycle and occasionally infect the *I. pacificus* population. It is not clear, however, whether wood rats and kangaroo rats represent the main source of spirochetal infection within the *I. pacificus* population.

The force of transmission of the agent of Lyme disease in western Europe tends to be weaker than in northeastern North America. European *I. ricinus* ticks transmit these microbes less efficiently than do their North American counterpart, *I. dammini*, because each trophic stage feeds most frequently on different kinds of hosts. Larvae tend to parasitize rodents, and nymphs to feed on medium-sized mammals, birds, and lizards. Adults feed mainly on deer or sheep. So few of these rodents are

parasitized by nymphs that the EIR may be limited. Nevertheless, certain kinds of rodents harbor sufficient infectious nymphs to ensure perpetuation of the pathogen. Edible dormice (*Glis glis*) and black-striped mice (*Apodemus agarius*) serve as particularly efficient reservoirs because they are frequently infested by both the infectious and pathogen-acquiring stages of the wood tick. Norway rats (*Rattus norvegicus*), too, may support transmission of the Lyme disease agent in particular urban sites. Because shrews and voles are far more abundant than mice in Sweden, these small mammals may perpetuate the life cycle in certain Scandinavian sites. The relative importance of each kind of vertebrate host as a reservoir of infection differs according to local conditions.

In eastern Asia, Lyme disease spirochetes appear to circulate in a cycle involving the taiga tick (*I. persulcatus*) and rodents of the genera *Clethrionomys* and *Apodemus*. To date, solely *B. garinii* and *B. afzelii* have been isolated from tick vectors and rodent hosts inhabiting these regions. The bank vole (*Clethrionomys glareolus*) predominates in western Russia, whereas *C. rufocanus*, *C. rutilus*, and *Apodemus peninsulae* dominate further to the east. Although numerous *Borrelia* isolates have been derived from these hosts, their relative contribution to infecting the tick population by *xenodiagnosis* remains uncertain.

Co-infecting Pathogens

Although public attention has focused on Lyme disease, *Ixodes* ticks may transmit numerous other agents of human disease. Human babesiosis, a malaria-like illness, is caused by the protozoan parasites *Babesia microti* in North America and *B. divergens* in Europe. Signs of this illness become evident mainly among elderly or immunocompromised subjects and may be fatal if not treated promptly. Viruses of the tick-borne encephalitis complex induce a potentially fatal form of *encephalitis* endemic to Europe and Asia. More recently, a new member of this viral complex was discovered in North America; transmission was attributed to deer ticks. Finally, two closely-related pathogens (*Ehrlichia phagocytophila* and *E. equi* in

eastern and western North America, respectively) were recently implicated as agents of human disease. These rickettsial pathogens infect leukocytes, and human cases may also terminate fatally. The diverse array of pathogens transmitted by *Ixodes* ticks, thereby, severely burdens human health.

In northeastern USA, the agents of Lyme disease, human babesiosis, and human granulocytic ehrlichiosis perpetuate mainly in a cycle involving white-footed mice. Vector ticks, thereby, tend to acquire more than one of these microbes from reservoir rodents. This implies that individual human hosts tend to be vulnerable to coinfection. Serological surveys indicate that 10–60 % of Lyme disease patients had been coinfecting by *B. microti*. Interestingly, these pathogens tend to synergize in human hosts such that the resulting illness is more severe than would be anticipated as the sum of symptoms produced by each pathogen. More symptoms are experienced, and the duration of illness is prolonged. The particularly severe manifestations of *Ixodes*-borne disease that occur in certain enzootic sites may reflect a peculiar combination of coinfecting pathogens.

Antivector Interventions

Once established, local transmission cycles of tick-borne zoonoses tend to persist in the face of public health interventions. Various interventions, however, have been devised, and few of them appear promising. The following discussion describes selected strategies designed to reduce the public health burden presented by vector ticks.

Individual residents of enzootic sites may practice preventive measures that effectively reduce their risk of infection by tick-borne pathogens. They should: (1) avoid tick-infested habitats whenever feasible; (2) wear light-colored trousers with cuffs that are tucked into their socks; (3) apply tick-repellent containing DEET to exposed parts of their skin and permethrin to their clothing; (4) periodically examine the surface of their clothing and skin and remove any ticks that have attached using fine tipped forceps. Prompt removal of attached ticks generally aborts transmission because transmission of many of

these infections tends to require extended periods of host attachment. The arboviral agents may constitute an exception. Although the efficacy of these measures has not systematically been evaluated, they appear to provide an important degree of protection against tick-borne disease.

Depriving ticks of access to their main vertebrate hosts may effectively reduce the density of ticks. This intervention strategy, however, is practical solely in sites that such hosts would not rapidly reinvade. Deer inhabiting a study site on Great Island, MA were virtually eliminated, which resulted in decreased abundance of deer ticks. Host reduction proved to be effective largely because the relative isolation of the site restricted the movements of deer. Similar efforts on the mainland proved to be impractical and excessively costly. Thousands of small rodents, for example, were destroyed in Montana in order to suppress the density of American wood ticks (*Dermacentor andersoni*), the vectors of the agent of Rocky Mountain spotted fever. Any gains were transient, however, because wood ticks from nearby undisturbed sites rapidly reinvaded the intervention site. Antitick measures based on the removal of their vertebrate hosts require that the site be isolated in order to limit immigration from adjacent sites.

Although broad-scale applications of acaricides may destroy numerous ticks, environmental damage tends to result. Acaricidal applications focused around residential sites may alleviate the immediate tick burden. Residual pesticides such as carbaryl, chlorpyrophos, and diazinon temporarily render such sites virtually tick-free. Less toxic materials, containing pyrethroids, may also reduce tick density. These products, however, lack long-term residual activity and require at least monthly application to maintain satisfactory freedom from ticks. Regardless of the kind of acaricidal compound that is applied, pesticide resistance should always be anticipated. Intensive and extensive applications of killing chemicals can only be temporary. Loss of acaricide susceptibility renders acaricidal interventions inherently unsustainable.

Innovative strategies have been developed for delivering acaricides directly to the hosts of vector ticks. Various self-medicating devices for

destroying ticks on deer or other ungulates are in various stages of development and evaluation. In general, such devices deliver acaricide from a dispenser that the animal contacts when feeding on a bait contained within. Another host-targeted strategy distributes grain impregnated with systemic acaricides, such as ivermectin. When deer are the targets of such interventions, they must be habituated to the bait-station, and this requires delivery of large quantities of grain, frequently a maize-molasses mixture. This has the undesirable side effect of promoting the density of various rodents as well as the targeted deer, themselves. A cotton-baited acaricidal formulation has been implemented to target rodent hosts such as the white-footed mouse in eastern North America. This method is designed to reduce the force of transmission of *Ixodes*-borne pathogens by eliminating those ticks that feed on the rodent reservoirs. Host-targeted acaricidal formulations are attractive because they limit any environmental damage that might be induced by these biologically active chemicals.

Ticks are vulnerable to destruction by various parasitic or predatory organisms. Although certain *Dermacentor* and *Amblyomma* ticks secrete a pheromone that deters attack by ants, *Ixodes* lack such protection against predation. To the extent that fire ants are important predators of these ticks, their presence might benefit public health. A chalcid wasp (*Hunterella hookeri*) frequently parasitizes larval *Ixodes* ticks in northeastern North America and Europe and destroys them in their nymphal stage. Although these wasps infect as many as a third of the nymphal deer ticks in eastern North America where Lyme disease is enzootic, none infect spirochete- or *B. microti*-infected ticks. Efforts to use these wasps to reduce risk of Lyme disease, therefore, would fail. Certainly, tick densities seem unaffected in the face of this natural burden. The applicability of bio-control efforts against vector ticks remains speculative.

The density of vector ticks may be reduced by removing understory vegetation and leaf litter, either mechanically, chemically, or by fire. Where few buildings are present, the undergrowth or ground cover that shelters ticks is most readily

destroyed by burning. In a Massachusetts site, burning and mowing reduced deer tick densities by as much as 80 %. Similar efforts in Tennessee greatly reduced the density of Lone Star ticks. Safety considerations, however, limit the wide-scale application of this measure. Limited areas such as along a road, may be mowed, and this would seem to protect people from contact with ticks. The efficacy of this measure, however, remains ill-defined. Routine herbicidal applications are poorly tolerated by many people and may excessively harm the environment. While vegetation management provides effective protection against ticks, it must be reapplied on a yearly basis.

Ticks of Camels

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Amblyomma gemma, *Amblyomma variegatum*, *Dermacentor nuttalli*, *Hyalomma asiaticum*, *Hyalomma detritum*, *Hyalomma dromedarii*, *Hyalomma impeltatum*, *Hyalomma rufipes*, *Ornithodoros savignyi*, *Rhipicephalus evertsi*, *Rhipicephalus pulchellus*, and *Rhipicephalus pumilio*.

Ticks of European Ruminants

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Fauna Europaea (faunaeur.org) describes three main groups of ticks (1–4) on European ruminants.

1. **Species restricted to the Mediterranean area:**
 - (a) *Hyalomma annulatus*, *H. lusitanicum*, *H. marginatum*, *H. punctata*, *H. scupense*, *H. sulcata*
 - (b) *Rhipicephalus bursa*, *R. annulatus*
2. **Species occurring widely in the Palearctic:**
Ixodes ricinus
3. **Species in mild “Atlantic” regions:**
Dermacentor marginatus
4. **Other wider spread species:**
Rhipicephalus turanicus, *R. sanguineus*, *Dermacentor reticulatus*, *Ixodes hexagonus*, *I. gibosus*

Ticks: Impact of Infestation in Hosts

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Ticks have the following impacts on their animal hosts:

1. Some species may lead to paralysis or even to death as a consequence of the activities of the different compounds in the saliva.
2. Agents of disease (e.g., viruses, bacteria, parasites: ► *Theileria* spp., ► *Babesia* spp.) may be included in the saliva, thus transmitted may cause death or severe disease.
3. Engorging ticks may lead to considerable loss in body weight and/or milk production of infested animals. E.g., noninfested cows produced per day 2.81 l more milk than those infested with *Rhipicephalus* (syn. *Boophilus*) *microplus*. This effect is apparently based on a 9 ml milk loss per attached tick.
4. Loss of money due to damages at the biting sites which diminish quality of hides used for shoes, etc.

Ticks: Tick Paralysis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The disease described as tick paralysis is an ascending motor paralysis, which is induced by a partial, increasing neurotransmission due to the apparent blockade of ion channels involved in the depolarization of nerves. This disease represents a peculiar polyneuropathy, which starts shortly after the beginning of the tick's blood meal, spreads to the upper limbs and causes incoordination of movements and may lead (as consequence of bites of some tick species) to respiratory failure and/or even may lead to death.

The following ixodid ticks are especially known for their high-graded toxic saliva and their introduction of the so-called tick-paralysis: *Ixodes holocyclus* (Australia), *Ixodes scapularis*, *Dermacentor variabilis*, *Amblyomma americanum* (North America), *Amblyomma cajannense* (South America), *Ixodes ricinus* (Europe), and *Rhipicephalus sanguineus* (worldwide). Besides ixodid ticks also argasid ticks have been identified to produce toxins and to disseminate them during injection of saliva into the skin of their hosts: *Ornithodoros savignyi*, *O. capensis*, *O. brasiliensis*, *Argas walkeri*, *A. monolakensis*, and *Otobius megnini*.

Many other species (e.g., *Ixodes rubicundus* in South Africa) are also able to induce paralysis, if the hosts are infested by larger numbers of ticks fulfilling the rule of *Paracelsus* that *the dose makes the poison*.

The venomous activity of the tick saliva, which is predominantly used to keep the blood fluent

at the biting site, to avoid blood coagulation and to avoid pain, is mainly due to the different proteins in the saliva: defensins, lectins, cystatins, lipocalins, hyaluronidase, phospholipases, Kunitz-like peptides, metalloproteases, etc. Several of these proteins may act as venoms. Their inclusion into eggs shows their second range of activity (i.e., protection of the eggs of ticks from being ingested by insects, mice etc.) In this case, these compounds would have a clear direct venomous activity.

Ticks: Venomous Protein Families

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

In tick saliva the following venomous protein families have been found:

- CAP proteins
- Cystatins
- Defensins
- Hyaluronidases
- Kunitz-like peptides
- Lectins
- Lipocalins
- Metalloproteases
- Phospholipases
- Sphingomyelinases

Tight Junction

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes the region (zonula occludens) between the plasma membranes of two adjacent cells of the same individual or the zone between a host cell and an attacking parasitic unicellular stage. The contact of the adjacent cells is so close that there is no space in between thus fusing cells closely together and providing a selective barrier to the diffusion of substances between cells. However, in case of penetration of protozoans into host cells (see ► [moving junction](#)), these tight connections help protozoans to slip into cells without disrupting the host cell membrane.

► [Cystoisospora](#), ► [Frenkelia](#), ► [Besnoitia](#), ► [Caryospora](#), and the nematode ► [Trichinella spiralis](#) form intracellularly situated cysts within different tissues of their hosts. While the *T. spiralis* larva is always situated directly in the ► [cytoplasm](#) of its host cell (muscle fiber), the protozoan cysts are always surrounded by a ► [primary cyst wall](#), which derives from the original membrane of the ► [parasitophorous vacuole](#) (Figs. 1, 2, 3, and 4). In some cases, the parasitized host cell (e.g., ► [Besnoitia](#) species, ► [Globidium](#) species, *Sarcocystis ovifelis*) is covered (along its outer surface) by host cell material. This layer is called ► [secondary cyst wall](#). In trichinosis, such a secondary cyst wall may also be formed by defense cells of the host and may later introduce the calcification of the muscle fiber containing the worm larva. The stages inside the protozoan tissue-cysts are called ► [bradyzoites](#) (due to their slow division rate). They survive for years at a reduced metabolism and remain infectious (► [Toxoplasma gondii](#)).

Toll-Like Receptor 9 (TLR9)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This is a transmembrane receptor, which recognizes molecular patterns derived from pathogens (e.g., their DNA). This TLR9 is expressed in several cells involved in the immunization of a host and belong to the groups of monocytes, dendritic cells, or B lymphocytes.

Toltrazuril

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Generic name of the coccidiocidal product Baycox[®], that has been proven to eliminate coccidian infections in chicken, pigeons, cattle, dogs, cats, rabbits, rodents and fish. It belongs to the chemical group of triazintrions.

Tomit

Other name for ► [theront](#) of ► [Ichthyophthirius](#).

Top Ten of Human Parasites

According to WHO (<http://www.who.int>) ► [Ascaris](#), ► [hookworms](#), ► [malaria](#) agents,

► [Trichuris](#), ► [amoebae](#), filarial worms, schistosomes, *Giardia*, trypanosomes, and ► [Leishmania](#) are the 10 most important agents in human diseases, together causing more death than anything else apart from HIV/AIDS and tuberculosis (<http://www.jama.com>). Some other worms (e.g., ► [Enterobius vermicularis](#)) are as numerous but not as pathogenic. One in 10 humans on this earth suffers from one or more of these major tropical diseases.

Toscana Virus

Christian Melaun^{1,2}, Antje Werblow^{1,3} and Sven Klimpel⁴

The Toscana virus (TOSV, sometimes also called Tuskany virus), an arbovirus of the genus *Phlebovirus* including Sicilian virus, Naples virus, and Punta Toro virus, is a serotype of Sandfly fever, which is widely distributed in the Mediterranean region. Among the sandfly fever viruses, the Naples serocomplex and the Sicilian serocomplex are the two main serocomplexes associated with human diseases. Toscana virus is more diverse than other well-studied phleboviruses (for example, Rift Valley fever virus). All Phleboviruses belong to the

Bunyaviridae family and are enveloped RNA viruses with three helicoidal nucleocapsids (80–120 nm diameter) and grow in the cytoplasm of the host cell. The tripartite genome consists of negative-sense RNA divided into S (small)-, M - (medium)-, and L (large)-segments. The L-segment is about 6,400 nucleotides in length and encodes for the viral polymerase. The M-segment with about 4,200 nucleotides encodes for structural glycoproteins, whereas the S-segment encodes for nucleic proteins and is about 1,900 nucleotides in length.

Toscana virus was isolated for the first time in 1971, from the sandfly *Phlebotomus perniciosus* Newstead, 1911 in Monte Argentario, Toscana. But it was in 1983, when it was recognized as a causative agent of neurological disease in humans, after it was isolated for the first time from a young woman with lymphocytic meningitis. Later, the virus was also isolated from the sandflies *Phlebotomus perfiliewi* (Parrot 1930) and *Sergentomyia minuta* (Rondani 1843). However, *P. perniciosus* is probably the most common insect vector of the Toscana virus, as it is one of the most abundant sandflies in Southern Europe and entering northwards Germany. Toscana virus infections are often asymptomatic, but can cause also high fever, headaches, muscle aches, and neck stiffness. It is also the main cause for meningitis or meningo-encephalitis during summertime in Italy and one of the three most prevalent viruses associated with meningitis in that period. Cases with meningitis or meningo-encephalitis have been reported also for other countries of the south European region: Portugal, Spain, Cyprus, Greece, and France; a study in Turkey revealed also positive serologies for that country. Due to climate change, the distribution of Toscana virus is evolving (Fig. 1), and pathogenicity may be higher in nonexposed populations outside areas of current prevalence (Mediterranean Basin). Tourists returning from Mediterranean countries imported the virus to other countries so that there are also reported cases from, e.g., Sweden, Germany, and Switzerland. Studies in Spain indicated that Toscana virus occurs more often in rural areas (26.7 %) than in urban (20.6 %).

Toscana Virus, Fig. 1 Toscana virus distribution: *dark grey*: native infections; *medium grey* imported cases; *light grey*: seropositive cases in population

Seroprevalence studies revealed that depending on the country but also on the region the prevalence ranges from 3 % in northern Italy and up to 26.7 % in rural areas in Spain. So far, the suggested reservoirs for the virus are the vectors themselves. In this context, it is noteworthy that veneral transmission from infected males to infected females as well as transovarial transmissions could be demonstrated in the laboratory by viral isolation from male sandflies. However, it seems that the virus cannot be maintained just by vertical transmission as a progressive decline could be observed from generation to generation. A possibility would be bats (Chiroptera), as except humans they represent the only known vertebrate host for the virus, but their role as a possible reservoir host is unknown yet. Regarding the feeding behavior of *Sergentomyia*

minuta another possible option as a reservoir host can be reptiles, as *S. minuta* feeds on lizards. A new lineage of TOSV, divergent from the Italian prototype, has recently been reported in Spain.

Toscana virus infection laboratory diagnosis can be performed through the use of ELISA, immunofluorescence, and/or neutralization tests. In the acute phase of the infection, the methods of choice are nucleic acid amplification techniques for diagnosing viral meningitis from cerebrospinal fluid samples. Such molecular methods bring the advantage that they are rapid and sensitive and particularly, in contrast to traditional methods, like virus isolation by cell culture, the viability of the virus in the clinical specimen does not influence the diagnosis. Additionally, a sensitive real-time PCR has been developed for diagnosis of suspected cases of TOSV infection.

The Toscana virus (TOSV, sometimes also called Tuscany virus), an arbovirus of the genus *Phlebovirus* including Sicilian virus, Naples virus, and Punta Toro virus, is a serotype of sandfly fever, which is widely distributed in the Mediterranean region. Among the sandfly fever viruses, the Naples serocomplex and the Sicilian serocomplex are the two main serocomplexes associated with human diseases. Toscana virus is more diverse than other well-studied phleboviruses (e.g., Rift Valley fever virus). All phleboviruses belong to the Bunyaviridae family and are enveloped RNA viruses with three helical nucleocapsids (80–120 nm diameter) and grow in the cytoplasm of the host cell. The tripartite genome consists of negative-sense RNA divided into S (small)-, M (medium)-, and L (large)-segments. The L-segment is about 6,400 nucleotides in length and encodes for the viral polymerase. The M-segment with about

Toscana Virus Generalities,

Fig. 1 Toscana virus distribution: *dark gray*, native infections; *medium gray* imported cases; *light gray*, seropositive cases in population

4,200 nucleotides encodes for structural glycoproteins, whereas the S-segment encodes for nucleic proteins and is about 1,900 nucleotides in length (Fig. 1).

Toscana virus was isolated for the first time in 1971, from the sandfly *Phlebotomus perniciosus* Newstead, 1911 in Monte Argentario, Toscana. But it was in 1983 when it was recognized as a causative agent of neurological disease in humans, after it was isolated for the first time from a young woman with lymphocytic meningitis. Later, the virus was also isolated from the sandflies *Phlebotomus perfiliewi* Parrot, 1930 and *Sergentomyia minuta* Rondani, 1843. However, *P. perniciosus* is probably the most common insect vector of the Toscana virus, as it is one of the most abundant sandflies in southern Europe and entering northward Germany. Toscana virus infections are often asymptomatic

but can cause also high fever, headaches, muscle aches, and neck stiffness. It is also the main cause for meningitis or meningoencephalitis during summertime in Italy and one of the three most prevalent viruses associated with meningitis in that period. Cases with meningitis or meningoencephalitis have been reported also for other countries of the south European Region: Portugal, Spain, Cyprus, Greece, and France; a study in Turkey revealed also positive serologies for that country. Due to climate change, the distribution of Toscana virus is evolving, and pathogenicity may be higher in nonexposed populations outside areas of current prevalence (Mediterranean Basin). Tourists returning from Mediterranean countries imported the virus to other countries, so that there are also reported cases from, e.g., Sweden, Germany, and Switzerland. Studies in Spain indicated that Toscana virus

occurs more often in rural areas (26.7 %) than in urban (20.6 %). Seroprevalence studies revealed that depending on the country, but also on the region, the prevalence ranges from 3 % in northern Italy up to 26.7 % in rural areas in Spain. So far, the suggested reservoirs for the virus are the vectors themselves. In this context, it is noteworthy that venereal transmission from infected males to infected females as well as transovarial transmissions could be demonstrated in the laboratory by viral isolation from male sandflies. However, it seems that the virus cannot be maintained just by vertical transmission as a progressive decline could be observed from generation to generation. A possibility would be bats (Chiroptera), as except humans they represent the only known vertebrate host for the virus, but their role as a possible reservoir host is unknown yet. Regarding the feeding behavior of *Sergentomyia minuta*, another possible option as a reservoir host can be reptiles, as *S. minuta* feeds on lizards. A new lineage of TOSV, divergent from the Italian prototype, has recently been reported in Spain.

Toscana virus infection laboratory diagnosis can be performed through the use of ELISA, immunofluorescence, and/or neutralization tests. In the acute phase of the infection, the methods of choice are nucleic acid amplification techniques for diagnosing viral meningitis from cerebrospinal fluid samples. Such molecular methods bring the advantage that they are rapid and sensitive and particularly, in contrast to traditional methods, like virus isolation by cell culture, the viability of the virus in the clinical specimen does not influence the diagnosis. Additionally, a sensitive real-time PCR has been developed for diagnosis of suspected cases of TOSV infection.

Toxascaris leonina

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *toxon* = crescent-shaped, *ascaris* = intestinal worm, *leon* = lion.
T. leonina occurs with a low host specificity in many canids and felids, reaches as females 10 cm or males 7 cm, and is characterized by very long and small cervical wings (Fig. 1). The development is direct without a wandering phase inside the host after oral uptake of larva-containing eggs.

Toxocara

Name

Greek: *toxon* = halfmoon-/crescent-shaped, *kara* = head, protrusion.

Toxascaris leonina, Fig. 1 SEM of the anterior end with cervical wing longer than those of *T. canis*

Toxocara, Table 1 Important species of the genus *Toxocara*

Species	Length of adult worms (µm)		Size of eggs (or larvae) (µm)	Final host/Habitat	Intermediate host	Prepatent period in final host (weeks)
	f	m				
<i>Toxocara canis</i>	120–180	100–120	90 × 75	Dogs/Small intestine	Mice	4
<i>T. cati</i> / <i>T. mystax</i>	100	60	75 × 70	Cats/Small intestine	Mice	8
<i>T. vitulorum</i>	210–270	150–250	69–93 × 62–77	Cattle/Small intestine	–	3

Toxocara, Fig. 1 Life cycle of ► *Toxocara canis* (*T. cati* is similar except for 8). 1, 2 Adults (► **Nematodes**, Table 1), which are characterized by species-specific lips and by typical cervical ► **alae** (center), live in the small intestine of their hosts, producing large numbers of eggs which are passed unembryonated (2) with the host's feces. The eggs are characterized by a relatively thick shell which is provided with a mammillated surface. 3, 4 The first and second larval stages are formed within the eggshell under favorable conditions. 4.1, 4.2 If humans, inadequate hosts (4.2), or even immune dogs swallow such eggs, the L₂ hatch from the eggs in the intestine, penetrate through the intestinal wall, and migrate through the body (*larva migrans visceralis*), but there is no further development. Such larvae may become included in ► **granulomes** and

remain infective to final hosts (5) for a long time. 5–8 When nonimmune final hosts swallow the eggs (4), the L₂ hatches from the egg inside the intestine, penetrates the intestinal wall, and is transported via the bloodstream to the liver and lung, where it molts to L₃ and L₄. The L₄ finally reaches, via the trachea, the intestine and matures. If the host is provided with a low immunity, the larvae do not complete the lung migration, but wander through the body and remain “dormant” for a long period. During pregnancy the dormant larvae are activated (8) by host hormones, reenter the circulatory system, are carried to the placenta, and penetrate into the fetus, which thus becomes prenatally infected. Infections from the mother's milk are also common

Toxocara, Fig. 2 Adult *Toxocara canis*-worms in the intestine of a dog

Toxocara, Fig. 4 SEM of the anterior end with short cervical wings (= alae), *T. canis*

Toxocara, Fig. 3 LM of a bundle of adult worms (*Toxocara canis*)

Classification

Genus of ascarid nematodes of carnivores.

Important Species

Table 1 (p. 1420), Figs. 1, 2, 3, and 4 (pp. 1422, 1423).

Life Cycle

Figure 5 (p. 1421).

Toxocara, Fig. 5 Egg of *Toxocara canis* containing a larva

Geographic Distribution/Epidemiology

Worldwide, especially common in buffaloes in the tropics and subtropics, but rather rare in cattle in Europe.

Morphology/Life Cycles

Only *Toxocara vitulorum* (the so-called large roundworm) reaches maturity in ruminants. The females and males parasitize in the small intestine and measure about 20–30 cm in length as females and 15–25 cm as males. Morphologically, the adult worm can be differentiated from *Ascaris suum* by the fact that their three lips are considerably smaller than the rest of the body, so that there appears an aspect of shoulders in contrast to aspects in ► *A. suum*. The typical eggs with their rough surface (Fig. 1) measure 70–95 × 60–75 µm and are unembryonated when excreted with the feces. The further development is similar to that of ► *Ascaris suum*, however, also prenatal and galactogeneus transmission of larvae had been described in *T. vitulorum*.

Disease

- [Toxocariasis, Man](#), Toxocarosis, Animals,
- [Visceral Larva Migrants, Man](#).

Toxocara (syn. *Neoascaris*) *vitulorum*

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Name

Greek: *toxón* = bow; *kara* = head; Latin: *vitula* = small female calf; English: large roundworm of cattle.

Symptoms of Disease (Toxocariasis)

In cases of low-graded infections, symptoms are scarce or even absent. Severe infections may lead to the following symptoms: stinking breath, reduced feeding, cough, pneumonia (due to wandering larvae), diarrheas, phases of obstipations, flatulence, and ileus verminosus. Penetrations of the intestinal wall induce peritonitis and even death may occur (especially in highly infected calves).

Diagnosis

Microscopical determination of the typical *Toxocara* eggs (Fig. 1) using concentration methods (e.g., ► [flotation](#), ► [S.A.F.C.](#), ► [M.I.F.C.](#)). Since the feces smell like butyric acid or like being mixed with alcohol, the air in stables

***Toxocara* (syn. *Neoascaris*) *vitulorum*, Fig. 1** Light micrographs of typical worm eggs and an egg of a mite, which often occur in food. LA larva, PF polar plug

with several infected animals may smell unusually.

Infection

Oral uptake of eggs, within which the infectious larva 2 had been developed within 10–14 days. However, also prenatal infections and galactogeneous infections of calves are possible.

Prophylaxis

Regular cleaning of the stables from feces; quarantine of imported animals.

Incubation Period

Rare lung symptoms after 4–7 days, intestinal symptoms start 2–4 weeks after infection

depending on the amount of ingested infectious eggs.

Prepatent Periods

After galactogeneous infections 3–4 weeks, otherwise 4–6 weeks.

Patency

3–5 months.

Therapy

The treatment of calves may start after the second week with benzimidazoles or macrolytic lactones.

Toxocara canis

This ascarid worm of dogs occurs worldwide, reaches as adults a size of 10–12 cm as male or 12–18 cm as female, and is characterized by apical cervical wings (► *Toxocara*, Fig. 4). The adult worms are found in the small intestine, where the females excrete the 75–90 µm eggs (► *Toxocara*, Fig. 5), which develop within 2 weeks inside the infectious larva 3. After oral uptake this larva wanders via liver, heart, lung, and trachea finally again into the small intestine, where

***Toxocara canis*, Fig. 1** Swollen belly of an infected young dog (Courtesy of the late Professor Stoye)

maturity is reached 27–35 days after infection. Females may infect their puppies inside the uterus or via milk. In case humans swallow infectious eggs, a ► *larva* migrans interna-syndrome may occur. Infected puppies may suffer from swollen belly when heavily infected (Fig. 1, p 1424).

See Fig. 1.

Toxocara canis Embryonated Worm Eggs,
Fig. 1 Embryonated worm eggs

Toxocara cati

Synonyms

T. mystax

This is the ascarid worm of cats (females, 10 cm; males, 6 cm). Its cervical wings are rather wide and striped (► *Toxocara*/Fig. 4). The development includes a wandering phase as in *T. canis*. Larvae may also induce in humans the symptoms of larva migrans interna.

Toxocara Species of Carnivores

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *toxos* = arch, bow; *kara* = head. Latin: *canis* = dog.

Geographic Distribution/Epidemiology

Worldwide, high prevalence rates occur especially in breeds of cats and dogs. Young **dogs** showed

infection rates of up to 80 %, young foxes up to 70 %, while 10 % of older dogs (in towns) were important as permanent egg distributors close to playgrounds. Cats in households and in breeding institutions showed prevalence rates of 40–70 % and thus are also important contaminants of playgrounds in towns or in private gardens.

Morphology/Life Cycles

The carnivores inside houses or those close to houses such as dogs, cats, foxes, and other carnivores are parasitized by several ascarid nematodes:

- (a) ***Toxocara canis***: These worms are found in dogs and foxes, respectively, in wolves (♀ = 12 cm up to 18 cm; ♂ = 8 cm up to 10 cm long; Figs. 1, 2, and 3); their cervical wings (= alae) (Fig. 3) appear striated and reach a length of about 2.5–3 mm. Alae are not present in larvae.
- (b) ***Toxocara mystax* (syn. *T. cati*)**: Worms (♀ = 12 cm; ♂ = 3–7 cm) parasitize in the intestine of felids and is the most common toxocarid worm of cats worldwide. Their short cervical wings (= alae) appear rather broad.
- (c) ***Toxascaris leonina*** is not very host specific and is found in a broad spectrum of felids and canids. The females reach a length of 12 cm, the males of up to 7 cm. Their cervical wings (= alae) are rather long (Fig. 4). The esophagus of this species does not show a bulbous enlargement as the other toxocarids and their life cycle does not run like that of *T. canis* (Fig. 1), since the larvae stay after hatch in the intestine and develop there into the adult stage without a migration through the body as it is the case in *T. canis*.
- (d) ***Bayliascaris procyonis***: toxocarid worm of raccoons, see **own** keyword *Bayliascaris*.

The eggs of these toxocarid nematodes are excreted unembryonated and are characterized by their typical thick shell of brownish color reaching a size of about 85–90 × 60–75 μm (Fig. 5). Under appropriate temperatures

Toxocara Species of Carnivores, Fig. 1 Life cycle of *Toxocara canis* (*T. cati* is similar except for 8). 1, 2 Adults (► **Nematodes**), which are characterized by species-specific lips and by typical cervical ► **alae** (center), live in the small intestine of their hosts, producing large numbers of eggs which are passed unembryonated (2) with the host's feces. The eggs are characterized by a relatively thick shell which is provided with a mammilated surface. 3, 4 The first and second larval stages are formed within the eggshell under favorable conditions. 4.1, 4.2 If humans, inadequate hosts (4.2) or even immune dogs swallow such eggs, the L₂ hatch from eggs in the intestine, penetrates through the intestinal wall and migrates through the body (larva migrans visceralis), but there is no further development. Such larvae may become included in

► **granulomes** and remain infective to final hosts (5) for a long time. 5–8 When nonimmune final hosts swallow the eggs (4), the L₂ hatches from the egg inside the intestine, penetrates into the intestinal wall and is transported via the bloodstream to liver and lung, where it molts to L₃ and L₄. The L₄ finally reaches, via trachea, the intestine and matures there. If the host has a low immunity status, the larvae do not complete the lung migration, but wander through the body and remain “dormant” for a long period. During pregnancy, the dormant larvae are activated (8) by host hormones, reenter the circulatory system, are carried to the placenta and penetrate into the fetus, which thus becomes prenatally infected. Infections via mother's milk are also common

Toxocara Species of Carnivores,

Fig. 2 Macrophoto of *Toxocara canis* worms obtained from feces of a treated dog

Toxocara Species of Carnivores,

Fig. 3 Scanning electron micrographs of the anterior end of *Toxocara canis* showing the three lips of the mouth and the bilateral cervical wings of the cuticle

(15–30 °C) and sufficient humidity the larvae are formed rather quick inside the eggs, which takes about 3–5 days in *T. leonina* and 10–15 days in *T. canis* and *T. mystax* (but it takes 7–8 weeks at 12–18 °C). In *T. leonina* and *Bayliascaris procyonis* the hatched larva 1 enters the intestinal wall, where it develops via larva 2 to larva 3, which returns to the intestinal lumen and finally reaches maturity there. In both *Toxocara* species and in *B. procyonis* the hatched larvae enter the intestinal wall, start the migration through the body (**larva migrans visceralis**), induce damages in eyes, brain etc., and are often included in

so-called granulomas, where they are finally destroyed (except for those in the brain) by attacking eosinophilic granulocytes. In livers these granulomas appear as so-called ► [milk spots](#) (see ► [Ascaris suum](#)).

The most common way of infection in *Toxocara canis* is the prenatal infection of embryos inside the placenta. Dormant larvae 2 inside the muscles of a pregnant dog are apparently activated by hormones and migrate via placenta into the liver of the embryo. Just after birth of the new host these larva 3 start their migration via heart – lung – trachea – esophagus to the small

Toxocara Species of Carnivores, Fig. 4 Scanning electron micrograph of the anterior end of an adult worm of *Toxascaris leonina*

intestine, where they reach maturity within 14–23 days.

Newborn puppies of dogs are often infected (by means of galactogenous transmission = when sucking mother's milk containing larvae 3). This seems the second one of the most important pathways of infection.

Symptoms of Disease (Toxocariosis, Toxocariasis)

1. **Young infected dogs** die very often during the first 3 weeks when inhaling vomited material in cases of infections with high numbers of worms inside their intestines (Figs. 6 and 7). Further typical symptoms are: coughing, acute abdomen, slimy and nonformed feces, loss of weight, rhachitis, symptoms due to deficits of vitamin D, repeated vomiting, rough hair, etc.

2. **Older dogs** mostly show only symptoms of disease in the case of a first infection or in the case of a weak immune system, since during an existing immunity hatched larvae are killed when starting the penetration of the intestinal wall. Blood examinations show eosinophilia.
3. **Cats** show mostly similar symptoms like dogs, however, their severity remains considerably lower than that in dogs. Leading symptoms are rhachitic symptoms and loss of hair especially in the case of young animals.
4. **Humans** suffer from the effects of migrating larvae, if these stages enter important organs such as brain, lung, eyes, etc.

Diagnosis

This can be done by isolation of the typical eggs from the feces by help of concentration methods (S.A.F.C., ► [M.I.F.C.](#)) or by observation of fecally excreted worms, respectively, by expectorated young worms. The eggs are typical for the group, appear brownish with a thick, rough shell and measure about $90 \times 75 \mu\text{m}$ (Fig. 6).

Infection

- (a) Prenatal way (in *Toxocara canis*; Fig. 1).
- (b) Galactogeneous way via mother's milk.
- (c) Oral way by ingesting larvae 3 enclosed in muscles of paratenic hosts.
- (d) Oral uptake of embryonated eggs from feces of infected animals. This pathway is also used when humans become infected during such procedures.

Prophylaxis

Regular deworming of young animals (2, 4, 12 weeks after birth and later 3–4 times per year). Treatment of pregnant female dogs 2 and 4 weeks postpartum, respectively, 40 and 10 days before birth. Elimination of feces, cleaning of soils with hot steam/water (60°C) once a week. **Attention:** Humans may become infected.

Toxocara Species of Carnivores, Fig. 5 Nematode, mite and pentastomid eggs occurring in dog feces. Note that the eggs of *Toxascaris leonina* (g) show a smooth surface and that *Toxocara canis* (h) shows a rough surface. (a) *Capillaria putori*, (b) *Trichuris vulpis*, (c)

Toxocara Species of Carnivores, Fig. 6 Macrophoto of an intestine of a dog puppy, which died due to huge numbers of *Toxocara canis* worms

Toxocara Species of Carnivores, Fig. 7 Dog puppy suffering from a huge infection with *T. canis* worms showing the symptoms of an acute abdomen

Incubation Periods

- Young dogs: 1–2 days
- Older dogs: 5–7 days
- Cats: 3–7 days

Prepatent Periods

Highly variable (according to the different pathways of infection).

First infection of dogs	4–5 weeks
Prenatal infection	3–4 weeks
Infection with <i>Toxocara mystax</i>	8 weeks
Infection with <i>Toxascaris leonina</i>	10 weeks

Patency

Variable: weeks – months.

Therapy

The treatment of infections with persisting adult worms in cats and dogs is satisfying, however, wandering stages are only killed by a few anthelmintics.

Animals

1. Piperazine salts (~150–200 mg/kg body weight) kill adult worms in young dogs.

2. A broad spectrum of compounds such as **nitroscanate** (1×5 mg/kg for dogs), **flubendazole** (22 mg/kg), **levamisole** (5 mg/kg), or **pyrantel** (1×5 mg/kg for dogs; 1×20 mg/kg for cats) kills adults and has some effects on larval stages.
3. Another broad spectrum of compounds such as **benzimidazoles** kills not only nematodes but also tapeworms: fenbendazole ($3 \text{ days} \times 50 \text{ mg/kg}$) or **mebendazole** ($2 \times$ daily for 3–5 days).
4. The combination **praziquantel** + **pyrantel** + **febantel** (1×1 tablet per 10 kg bodyweight) can be used for adult and young dogs as well as for pregnant female dogs.
5. Prenatal infections and galactogeneious infections can be treated with **selamectin** (6 mg/kg bodyweight, spot on) or by help of **moxidectin** or **milbemycinoxim**.

Humans

Toxocariasis, Man

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Synonyms

Visceral Larva Migrans (VLM). See [Toxocara](#) species of carnivores.

Name

Greek: *toxón* = bended structure; *kara* = head (= worms with bended, curved anterior end); *mystax* = beard; *catta* = cat; Latin: *canis* = dog; English: dog roundworm.

Geographic Distribution/Epidemiology

Worldwide hundred thousand humans are infected (especially often children).

Morphology/Life Cycle

The nematode roundworms ► [Toxocara canis](#), *T. mystax* syn. *cati*, and *Baylisascaris procyonis* do not reach maturity in humans, who have ingested larvae containing eggs from cat or dog feces (Fig. 1). Inside the intestine, the larvae hatch from the eggs, penetrate the intestinal wall, and are finally distributed all over the body. At this stage, they may measure up to 1–5 mm and are found in many organs (e.g., lung, liver, muscles, eye, or even brain). These wandering larvae are called **larva migrans interna** respectively **I. m. visceralis**.

Toxocariasis, Man, Fig. 2 Light micrograph of an egg of *Toxocara canis* already containing an infectious larva

Infection

Oral uptake of larva-containing eggs from feces of dogs or cats. Eggs might also be glueing in hair of dogs and cats but are also common on public playgrounds.

Prophylaxis

Since practically 20 % of all cats and dogs in households are infected during shorter or longer phases, it is recommended that they should be regularly dewormed at intervals of 3 months. The sand of sandboxes on playgrounds should be exchanged twice a year.

Incubation Period

Two to 3 weeks after ingestion of larvae-containing eggs, first symptoms may be noted, e.g., coughing, etc.

Prepatency

None, since there is no reproduction in humans.

Patency

Several months until the larvae are killed by the immune system.

Therapy

The efficacy of chemotherapeutical approaches are unclear. In cases of clear symptoms, therapy was tried with tiabendazole (2x 25 mg/kg bodyweight daily for 5–7 days) or albendazole (10 mg bodyweight daily for 5 days). In any case, especially in cases on non-opeatle eye infections, corticosteroids should be given additionally (Fig. 2).

English trivial name for ► *Toxocara* species, *Toxascaris* species, and *Baylisascaris* species.

Toxonemes

Former name for the ► micronemes (► *Coccidia*) of ► *Toxoplasma gondii*.

Toxoplasma gondii

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *toxon* = bent, crescentic structure; *plasma* = structure, mass; the species name was given in 1907 by the two French Army physicians Nicolle and Manceaux, since the bent half-moon-shaped trophozoite stage of this parasite was first discovered in the rodent species *Ctenodactylus gundi* in North Africa.

Geographic Distribution/Epidemiology

This parasite is distributed worldwide and has been described in practically all species of mammals with high infection rates. Thus, *T. gondii* is probably the most common parasite on earth. About 60–80 % of humans aged more than 60 years are infected and thus bear antibodies. In younger humans, the infection rates increase with increasing age. In immunocompromised people, *T. gondii* turned out to be the “killer no. 3” after *Pneumocystis jiroveci* and *Cryptosporidium* species. Thus, it is regarded as “opportunistic parasite.”

Morphology/Life Cycle

The life cycle of this parasite, which was first described in 1907, was unknown until 1969/1970, when several groups (e.g., Frenkel/Dubey in USA, Overdulve et al. in the Netherlands, Siims in Denmark, Piekarski and Boch/Rommel in Germany) had the same idea and proved that *Toxoplasma gondii* has a typical two-host life cycle involving cats (and relatives) as **final hosts** and a

huge number of mammals including humans as **intermediate hosts**. In the intestine of the final host, the typical coccidian phases (schizogony, gamogony, and sporogony) occur and end in the excretion of typical unsporulated oocysts within the feces, while in the intermediate host reproduction occurs by endogeny in macrophages (first phase) and later cyst formation in cells of muscles and of the brain (Figs. 1 and 2). The unsporulated spherical oocysts have a size of $12 \times 10 \mu\text{m}$ (Fig. 2). They develop within 4–7 days (depending on the temperature inside oocyst shells) two sporocysts each containing four sporozoites. Thus, these oocysts belong to the typical ► *Isospora* type. If these sporulated oocysts are orally taken up by humans or other intermediate hosts, the sporozoites hatch from the oocysts and are transformed into so-called ► *tachyzoites* (from Greek = *tachys* = quick, *zoon* = animal), which penetrate actively into macrophages (or are ingested) and start reproduction there by ► *endodyogeny* (a peculiar formation of two new tachyzoites). After a period of reproduction inside the lymph nodes, some tachyzoites migrate away and enter cells like muscle fibers and cells of the brain. Therein, they are transformed during repeated peculiar binary divisions (endodyogeny) into so-called bradyzoites (= slowly dividing cells). They were named by Jack Frenkel with the Greek term *bradys* = slow, since they divide slowly and thus form typical ► *tissue cysts*, which are situated intracellularly and are separated from the surrounding host cell material by a typical ► *primary cyst wall*, which, however, in contrast to that of ► *Sarcocystis* species does not show protrusions or peculiar fortifications. These tissue cysts survive for a long time (eventually years) inside the tissues of the intermediate hosts. In the case that cats ingest raw meat with such tissue cysts (e.g., mice), schizogony starts there and finally the cat produces again oocysts. If muscle cysts inside intermediate hosts (e.g., humans, omnivores) are ingested by other intermediate hosts, they develop at first an infection of macrophages and other reticuloendothelial cells and later again tissue cysts (Figs. 1–7).

***Toxoplasma gondii*, Fig. 1** Life cycle and transmission pathways of *Toxoplasma gondii*. The typical coccidian life cycle proceeds in the intestinal epithelium of felids (final host) which are infected by oral uptake of sporulated oocysts (2), ingestion of “pseudocysts” (4.1; 8) or tissue

cysts (6.1; 11) with meat of various intermediate hosts (of 2 types). 1 Unsporulated oocysts are excreted with feces. 2 ► **Sporulation** (i.e. formation of sporocysts and sporozoites) occurs outside the final host. These stages may become spread by transport hosts such as flies and

Symptoms of Disease (Toxoplasmosis)

(a) Humans

Most of human cases of infections with *T. gondii* remain symptomless, so that many people do not know that they had been infected and that they had already produced characteristic antibodies. This is due to the fact that initial symptoms of a toxoplasmosis are very unspecific (e.g., muscle pain, weakness, slight fever, slight lymph node swellings). The infections of old people may thus reach up to 80 %, and these are mostly not

aware of it, as was noted in systematical screening programs. On the other hand, infections with *T. gondii* may have severe consequences in other persons, and even life-threatening symptoms may occur:

1. **Acquired postnatal toxoplasmosis:** This disease starts either by oral uptake of sporulated oocysts within cat feces or by eating raw or undercooked meat of infected animals

Toxoplasma gondii, Fig. 1 (continued) cockroaches. 3 After ingestion of oocysts by intermediate hosts of type 1, the sporozoites are set free inside in its intestine and penetrate numerous types of intestinal cells (i.e. cells of the RES). 4 Inside the host cell the parasites reproduce by a typical ► binary fission (► endodyogeny) leading to “pseudocysts” which are filled with merozoites (e.g. ► tachyzoites). 4.1 After ingestion of such ► pseudocysts, cats may become infected. 5 Free ► merozoite (tachyzoite) in blood or lymph fluid after bursting of a pseudocyst. 5.1 When the first infection occurs in pregnant women (or animals), these merozoites may pass into the placenta and infect the fetus, leading to severe damage. 6 Formation of ► tissue cyst, mainly inside brain and muscle cells. After several endodyogenies these cysts

(waiting stages) contain numerous cyst merozoites (► Bradyzoites, ► Cystozoites) which are infectious for cats (6.1). 7–10 When carnivorous animals or man (intermediate hosts of type 2) ingest such tissue cysts with raw or insufficiently cooked meat, reproduction (see 3–6) via (9.1) may occur (see 5.1), leading to congenital toxoplasmosis. 11 Cats may also become infected by ingestion of ► tissue cysts from type 2 intermediate hosts. Then they pass oocysts after 3–5 days, whereas this prepatent period is longer after inoculation of pseudocysts (9–11 days). EN division by ► endodyogeny; HC host cell; N nucleus; NH nucleus of host cell; OC ► oocyst; PC ► primary cyst wall; PV parasitophorous vacuole; RB residual body; SP sporozoite; SPC sporocyst (for related species see ► Coccidia

***Toxoplasma gondii*,**

***Toxoplasma gondii*,**

Fig. 5 Transmission electron micrograph of a tachyzoite of *T. gondii* in negative staining. Since the pellicle had been skipped during preparation, the terminal conoid and the polar ring with the attached 22 subpellicular microtubules become visible

containing tissue cysts (Fig. 1). After an incubation period of about 2–3 weeks, the following symptoms may occur:

- Lymph node swellings
 - Affections of eyes (iridocyclitis, chorioretinitis)
 - Infection of the brain (meningoencephalomyelitis)
 - Infection of visceral organs (intestinal pneumonia, hepatitis, myocarditis, enterocolitis, myositis, and/or skin exanthemes)
2. **Congenital (connatal) toxoplasmosis:** Severe symptoms will only occur in the case when the mother is first-time infected during pregnancy. However, according to the estimation of the

German health authorities, about 6,000–7,000 cases of first infections occur per year among pregnant females. In about 50 % of these cases, the parasites enter the embryos and introduce in about 1,500 cases medium to severe damages. Different fetopathies were observed such as hydrocephalus, calcifications, damages of the ocular nerve, etc. Early births or abortions may become common reactions. Even if damages due to *Toxoplasma gondii* infections were not noted immediately after birth, many children start to show several symptoms up to 20 years later, when, e.g., eye deficiencies had slowly developed and became obvious.

Diagnosis

Acute infections of humans can be diagnosed by Giemsa-stained smears of punctures of lymph

nodes, blood, or other tissues. However, serological methods have a significantly higher importance:

(a) Determination of an infection:

This can be done by control of the antibody classes IgM and IgG. A **fresh infection** is characterized by the earlier occurrence of IgM. Are these antibodies lacking or is their amount lower than that of the IgG group an **older infection** has been determined. IgM antibodies were proven by use of the following methods:

- Indirect immunofluorescence test (IIFT)
- Double-sandwich IgM-ELISA (DSIgM-ELISA)
- Reverse enzyme immune assay (REIA)
- Immunosorbent agglutination assay (ISAgA)
- Enzyme immune assay (EIA)

All these tests show an infection.

The IgG antibodies may be measured by help of the following methods:

- Complement binding reaction (CBR)
- Dye test according to Sabin and Feldman (SFT)
- Indirect immunofluorescence test (IIFT)
- Enzyme-linked immunosorbent assay (ELISA)
- Direct agglutination test (DAT)

(b) Diagnosis of a first infection during pregnancy:

Toxoplasma gondii, Fig. 6 Light micrograph of a tissue cyst of *T. gondii* in the brain being filled with thousands of bradyzoites

Toxoplasma gondii, Fig. 7 Section through a *T. gondii* cyst in a muscle fiber. Note that below the primary cyst wall a zone of granular material is situated (green) surrounding the cross-sectioned bradyzoites

During each regular visit of a pregnant woman to her gynecologist, the blood should be investigated for antibodies against *T. gondii* in case she had no antibodies at the beginning of pregnancy. If there occurs later on a seroconversion, this indicates a fresh infection, which might be needed to become treated, since only fresh infections of previously noninfected pregnant women may endanger the health of the unborn fetus.

(c) Interpretation of the antibody reactions:

- *T. gondii* antibodies are visible by help of IIFT already 11 days after infection, and the highest titer values are reached after 3–4 weeks in tests like IIFT and SFT.
- Significant IgG antibody titers together with absent IgM antibodies plus a KBR of about 1:10 indicate an acute toxoplasmosis.

Attention: It is recommended to repeat any test, since variations in the tests may deliver eventually wrong results in borderline cases.

Infection

Infections of humans may occur in different ways:

1. Oral uptake of sporulated oocysts from cat feces or from hair of cats (cats like to lick both their anus and hair) (Fig. 2).
2. Oral uptake of oocysts that had been transported by flies from cat feces to human food or lips of babies.
3. Oral uptake of tissue cysts in raw or undercooked meat of animals (e.g., in mild raw ham, salami, sausages, steak tartare, etc.).
4. Intrauterine, diaplacental, or congenital transmissions. In case of the first infection of females during pregnancy, *Toxoplasma* tachyzoites may pass the placenta and enter the fetus, which may become severely infected. Tests have shown that already 1 % of the newborn were infected.
5. Blood transfusions from latent infected people to previously noninfected persons. However, this pathway is not very important in

Toxoplasma, since the blood of patients contains in general rather few trophozoites/tachyzoites.

Prophylaxis

Children, pregnant women (with negative *Toxoplasma* titers), as well as immunocompromised people should avoid contact with free-ranging cats, since these might be infected while feeding on infected mice. Freezing of meat (~30 °C) or cooking kills potentially contained parasites. Own house cats should be fed exclusively with cooked food. Very important is that seronegative pregnant women are regularly controlled for seroconversion.

Incubation Period

Hours to 2 days in the case of acute toxoplasmosis.

Prepatent Period

Depending on the pathogenicity and virulence of the *Toxoplasma* strain, it takes 2 days to several weeks to produce transmissible stages.

Patency

Years, since tissue cysts may persist in several tissues for a long time, while intracellular cysts are not recognized by the immune system. However, if, e.g., a muscle cyst is ruptured, the bradyzoites are set free, are able to enter neighbor cells, and form further cysts. Thus, symptoms of a new acute toxoplasmosis may occur, if macrophages ingest some of these bradyzoites.

Therapy

- (a) **Congenital toxoplasmosis:** Treatment is recommended in order to reduce the risk of

the late manifestations of the disease: pyrimethamine 1 mg/kg body weight at intervals of 2 days. In case of severe damages, initially 2 mg/kg body weight daily for 3 days combined with sulfadiazine (2×50 mg/kg body weight daily and in addition of folic acid 5 mg every second day). $2 \times$ per week control of therapy in asymptomatic infections should be done. Duration of the therapy: 6 months; in case of existing symptoms: up to 12 months. In cases of intolerability, spiramycine: 100 mg/kg body weight daily given in 2–3 doses. In cases of active infections of the brain or in cases of chorioretinitis combined with defects of the macula, additional administration of prednisolone (1–2 mg/kg body weight) is recommended, until signs of inflammation have disappeared.

(b) **Postnatal toxoplasmosis of immunocompetent persons:**

Slight symptoms such as lymphadenopathy do not need to be treated. However, treatment is recommended in the case of symptoms such as encephalitis, myocarditis, chorioretinitis, etc. or in cases of persisting general symptoms of disease. Then, therapy is recommended with pyrimethamine ($=2 \times 100$ mg on day 1; (children 2 mg/kg body weight) followed by daily administration of 25–50 mg (children 50–100 mg/kg body weight) combined with 10 mg folic acid per day. **Duration of the therapy:** 2–6 weeks (in cases of chorioretinitis = 4 weeks). In cases of chorioretinitis and danger of blindness (= destruction of the macula), the additional administration of prednisolone (1–2 mg/kg body weight/day) is recommended.

(c) **Toxoplasmosis during pregnancy:** Therapy should exclusively be done in cases of doubtless indication. Treatment can be started from the 20th week of pregnancy by use of pyrimethamine (50 mg on first day and then daily 25 mg sulfadiazine and folic acid as standard scheme plus blood control).

(d) **Toxoplasmosis of immunocompromised persons:** In case of AIDS patients, toxoplasmosis mostly leads to encephalitis with local lesions. In the case of transplantation patients also, cardiopulmonary symptoms may occur.

Therapy in cases of *Toxoplasma* encephalitis should be done as early as possible. Treatment is recommended with pyrimethamine (first day: 200 mg, then 75 mg (25–100 mg) daily) plus sulfadiazine (4 g daily in 4 doses) for at least 3 weeks. In addition, application of 10–15 mg folic acid should be done under constant blood control. In cases of an intolerance of sulfonamides, it is possible to combine pyrimethamine with clindamycine (4×600 mg per day). Atovaquone (4×740 mg/day) and azithromycine/pyrimethamine also showed good curing effects.

***Toxoplasma gondii*: Genome**

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Male and female gametes as well as tachy- and bradyzoites, which are produced in intermediate hosts (e.g., humans, pigs, etc.) possess 14 single chromosomes. Only just-fused zygotes (early oocysts) have a double set. Chromosomes I and VII exist both in an a and b version thus completing the originally seen 12 chromosomes. All chromosomes together have a total genetic size of 592 cM and an average map unit of 104 kb/cM. Details on the genome are collected in several databases for functional genomics analyses of different *Toxoplasma* strains: ApiDB, ToxoDB, EupathDB; <http://fulmal.hgc.jp>. These databases also contain data from other related apicomplexan parasites. The Experimental Proteomics Database (EPIC-DB; <http://toro.aecom.yu.edu/cgi-bin/defense/main.cgi>) is a publically available database that compiles *Toxoplasma* protein sequences.

***Toxoplasma gondii*: Stage Conversion**

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

T. gondii infections have two clinical phases:

1. **Acute phase**, which is characterized by repeated endodyogonies producing so-called ► **tachyzoites** inside ► **parasitophorous** vacuoles of various cell types of warm-blooded vertebrates.
2. **Chronic phase**, which is characterized by the formation and long persistence of ► **bradyzoites** in so-called tissue cysts inside brain and muscle cells (► **myotubes**).

Stage conversion to bradyzoites inside the tissue cysts in myotubes is correlated with the upregulation of the negative cell cycle regulators:

1. Testis-specific Y-encoded-like protein-2 gene expression (Tspyl2)
2. p21 (Waf1/Cip1) as well as with the downregulation of the cell cycle activator cyclin B1 and with absence of DNA synthesis

Toxoplasmosis of Swine

Anja Joachim¹ and Lukas Schwarz²

¹Department of Pathobiology, Institute of Parasitology, University of Veterinary Medicine Vienna, Vienna, Austria

²Department for Farm Animals and Veterinary Public Health, University Clinic for Swine, University of Veterinary Medicine Vienna, Vienna, Austria

***Toxoplasma* Infections in Swine**

Toxoplasma gondii is one of the most common protozoan parasites of warm-blooded animals with worldwide distribution. Numerous livestock species including pigs can become infected with

Toxoplasmosis of Swine, Fig. 1 *Toxoplasma* cyst in the brain of an infected animal (20× magnification)

Toxoplasma by ingestion of infectious oocysts, by transmission of tachyzoites during gestation, or by ingestion of infected meat or inner organs. After the acute phase of infection with rapid multiplication of tachyzoites in internal organs of the intermediate host, cysts containing bradyzoites develop in various tissues (Fig. 1) including muscles and remain infectious for prolonged time periods. In contrast, e.g., small ruminants, vertical transmission, and parasite invasion of the placenta and fetus seems rare in pigs (Dubey 1986), and subclinical infections frequently remain undetected. Clinical cases of acute toxoplasmosis have been described with anorexia, fever, cyanosis, dyspnea, and lameness in fatteners and abortion (Weissenböck and Dubey 1993; Kim et al. 2009), but these nonspecific symptoms are frequently attributed to others, more frequent causes of disease described in pigs.

The economic and medical importance of porcine toxoplasmosis is derived from the zoonotic nature of the infection. *T. gondii* is the most prevalent foodborne zoonotic parasite, with a disease burden in the range of campylobacteriosis and salmonellosis (Kijlstra and Jongert 2009; Jones and Dubey 2012). Humans can become infected upon ingestion of raw pork containing *Toxoplasma* cysts.

***Toxoplasma* Infections of Swine and Risk Factors of Human Infection**

Depending on age, geographic region, management type, and hygiene level, the prevalence of *Toxoplasma* infection in swine varies greatly; a single herd can be completely negative and partially or completely positive (see review by Jones and Dubey 2012; Torgerson et al. 2014). Despite the importance of human toxoplasmosis, currently no established test system for livestock or meat is in place. Seroprevalences reflect the risk of pigs to become infected; however, the risk of zoonotic transmission is not only determined by the infection prevalence in livestock but also by food-processing techniques as well as cultural (and individual) eating habits (e.g., as outlined in Edelhofer and Prossinger 2010). In addition, different strains of *T. gondii* have different host preferences; not all appear to have equal potential to infect humans. Studies from Slovakia indicate that pigs harbor primarily the virulent strain of genotype I (Turčėková et al. 2013), while human infections are mostly associated with type II (Sibley et al. 2009).

Diagnosis of *Toxoplasma* Infections in Pigs

Diagnosis of infection in pigs is achieved by serological detection of antibodies (using blood serum or meat juice as substrate) and by detection of parasite DNA in meat. The sensitive and specific detection of (viable) parasites in raw and processed pork is challenging since there are no in vitro markers for infectivity, and animal infection models are unsuitable for large-scale experiments.

Infection Risks for Pigs

Intensive management practices, with closed systems and no outdoor access for pigs, have led to a decrease of seroprevalences in slaughter pigs. However, more recently a growing demand for organic food and “animal-friendly” management

practices supports the contact between pigs and *T. gondii* oocysts in outdoor runs and pasture-like conditions, with the consequence of a renewed intensity of transmission and prevalence in “organic” pigs (see Jones and Dubey 2012). Besides soil-transmitted infection with oocysts (and probably poor hygienic conditions with barn access of cats and rodents as parasite carriers), raw milk from goats appears to be a risk factor for infection of pigs (see Jones and Dubey 2012). In addition to increase infection risks for pigs in certain management systems, the changes in meat processing may drive the transmission of *T. gondii* from pigs to humans – meat processed from a single animal is turned into several hundred portions so that, in theory, even prevalences <0.1 % in the worldwide population of fatteners (with around 1.3 billion/year being slaughtered worldwide) would provide several hundred million portions of infected meat for consumers.

Prevention

Although toxoplasmosis in pigs usually does not induce signs of clinical disease, the prevention of infection is paramount due to the high risk of transmission to humans via raw or undercooked pork. Table 1 lists the different sources of infection for pigs, risk factors, and prevention strategies. It can be assumed that *Toxoplasma* is

introduced on a farm via oocysts from an infected feline shedder or with surface water. Once the infection circulates in the local rodent (and cat) population, it must be assumed that infection of pigs can occur from various sources and that integrated measures are necessary to interrupt the transmission cycle. As farm cats regularly feed on rodents, they must be considered as a potential risk (especially young cats <1 year), and poor hygiene (including rodent control) further supports the transmission. Once oocysts are present in the environment, there is a continuous infection risk for pigs with outdoor access (as is mandatory for organic pig production systems) which can be reduced but not completely eliminated.

Transmission of *Toxoplasma* to humans via infected raw pork can be prevented by inactivation (freezing, cooking) of the meat and adequate food-handling hygiene (see Jones and Dubey 2012, for details). Since wild boar meat must be considered to be a potential source of infection due to frequent exposure of animals to oocysts, inactivation of cysts is mandatory before consumption.

Toxoplasmosis, Man

Pathology

Ignored for a long time, human toxoplasmosis was universally recognized as a genuine toxoplastic disease only 50 years ago while the *Toxoplasma* parasite was first identified at the beginning of the century. Not being highly virulent, ► *Toxoplasma gondii* is indeed a typical parasite which is found worldwide and often at very high prevalence. About half of the human population are asymptomatic carriers. The rapid multiplication of the invading ► tachyzoite stage, leads to a mild to subclinical phase. Recovery is associated with parasite sequestration into cysts containing ► bradyzoites located particularly within skeletal and heart muscle and in the central nervous system and remaining latent for life.

Infection originates from infected house cats (the definitive = final host) excreting oocysts in their feces or from undercooked meat with bradyzoites in tissue-cysts. Indeed, *T. gondii*

infection is also widespread in farm animals in particular, goat, sheep, and pigs and causes large financial losses in Australia, New Zealand, and England (Toxoplasmosis, Animals).

In man *T. gondii* disseminates from the site of entry via the bloodstream and the lymphatics to involve many tissues. The sites and character of lesions depend on the vascular supply of the tissue and the regenerative ability of the host cells. ► Tachyzoites proliferate approximately until immunity develops, at which time more slowly multiplying bradyzoites develop in tissue-cysts. These cysts are common in the brain, skeletal and heart muscle, and sometimes the retina. The cysts persist for months or years, in a biological sense waiting to be eaten by a cat; hence a chronic latent infection persists, and we have an infection immunity rather than a sterile immunity. The intact cysts are not chemotactic (► Pathology, Fig. 5A, B). However, leaking or ruptured cyst; elicit necrosis and an inflammatory reaction, interpreted as manifestations of hypersensitivity. The inflammatory reaction is mixed, involving neutrophils, lymphocytes, and macrophages, followed by fibrosis, and in the brain gliosis.

Two stages are distinguished in tissues: ► tachyzoites and ► bradyzoites. The tachyzoites multiply rapidly, destroying the cells they parasitize, giving rise to diffuse lesions, as in connective tissue or lungs, or to focal lesions, as in the liver and brain (► Pathology, Fig. 10). Tachyzoites destroying cells during acute toxoplasmosis lead to interstitial ► pneumonia, hepatitis, ► encephalitis, and myocarditis. A maculopapular rash may develop from small foci of *T. gondii* multiplying in the dermis. Many tissues may be only microscopically involved, and clinical symptoms do not draw attention to all of them. Lymphocytes and macrophages are the main inflammatory cells, with an admixture and neutrophils. When blood vessels are involved in the brain infarcts may result.

As already mentioned, individuals develop a nonsterilizing immunity with indefinitely latent infection when infected postnatally. This immunity is congenitally transferred to the fetus if acquired before pregnancy. However, at the occasion of an intercurrent infection or modification of

the host immunocompetence, slight such as pregnancy or more profound such as malignancies, organ transplants, or the acquired immune deficiency syndrome (► [AIDS](#)), mid-syndrome to severe life-threatening pathologies can be observed. Notably, when a primary infection is contracted by pregnant women, congenital infection can lead to ► [abortion](#) or neurological sequelae and ocular disorders in the fetus. While fetal death and abortion have been attributed to rapidly dividing tachyzoites, the CNS lesions and chorioretinitis in congenital infection or transplant or AIDS patients are caused directly by the cysts containing **bradyzoites** or by reactivation of this so-called dormant stage. The emergence of toxoplasmosis as a major opportunistic infection in AIDS leading to toxoplasmic encephalitis, in up to 48 % of the AIDS patients in areas where ► [T. gondii](#) is highly prevalent, has considerably stimulated interest in the past decade. Numerous scientists from all the fields of the biology have taken up the challenge and have begun to study various aspects of the host-parasite relationship. They have particularly concentrated their efforts on the understanding of the immune response against the parasite in order to develop vaccines and new immunotherapeutic approaches able to prevent (1) primary infection during pregnancy that eventually results in congenital infection in the fetus or abortion (i.e., immunity against the tachyzoite stage) (2) reactivated toxoplasmosis in immunocompromised patients (i.e., immunity against the cyst stage).

Lymphoreticular Hyperplasia

Lymphoreticular ► [hyperplasia](#) with prominent histiocytes is often present in the posterior cervical lymph nodes following febrile acute, or asymptomatic toxoplasmosis (► [Pathology](#), Fig. 11). This is not associated with tachyzoites or with cell or tissue necrosis; even bradyzoites in cysts are rare. Serologic tests indicate high antibody titers, and so the Lymphoreticular ► [hyperplasia](#) is interpreted as an immune reaction. The diagnosis can be suspected histologically and confirmed serologically, or vice versa.

Placental Toxoplasmosis

Placental toxoplasmosis occurs in 20–40 % of primary infections acquired during pregnancy, with microscopic but no gross lesions. This leads to toxoplasmosis in the fetus which most often is asymptomatic, but which in 10–20 % of infected babies is accompanied by clinical manifestation. Initially the lesions are generalized with hepatitis, splenomegaly, pneumonia, rash, anemia, extramedullary hematopoiesis, and failure to gain weight. As partial immunity is developed extraneural lesions subside. Sabin's tetrad, hydrocephalus, retinochoroiditis, intracerebral calcification, and psychomotor retardation characterizes persistent central nervous system infection.

Hydrocephalus

The pathogenesis of hydrocephalus in fetal and neonatal toxoplasmosis is unique. *T. gondii* tachyzoites reaching the central nervous system via the bloodstream give rise to microglial ► [nodules](#) throughout the brain (► [Pathology](#), Figs. 5, 6). In addition, the tachyzoites are disseminated through the ventricular system, resulting in widespread infection and necrosis of ependyma and subjacent tissues. This leads to obstruction in the narrow aqueduct of Sylvius (► [Pathology](#), Fig. 12A). As a consequence metabolic products of *T. gondii* and liquefied necrotic brain material accumulate in the lateral and third ventricles. *T. gondii* antigen in the ventricles diffuses through ependymal *ulcers* and interacts with antibody in the periventricular blood vessels (► [Pathology](#), Fig. 12B). These become surrounded with inflammatory cells as they approach the ventricles, further inwards the vessels leak protein and they become thrombosed close to the ventricles, leading to infarction necrosis. This in vivo antigen-antibody reaction and the zone of necrosis surrounding the lateral and third ventricles and the aqueduct are pathognomonic of congenital toxoplasmosis. Because the fourth ventricle fluid is drained through the open foramina of Luschka and Magendi; ependymal ulcers

are not accompanied by this reaction. Calcifications, often visible radiologically, develop in the areas of periventricular and aqueductal necrosis, and focally in areas of vasculitis throughout the infant's brain.

Retinochoroiditis

Retinochoroiditis (► [Eye Parasites](#)), found in infected babies, also occurs in children, adolescents, and adults. It rarely results from acute infection, but usually develops during ► [chronic infection](#), after *T. gondii* cysts persisting in the retina, disintegrate. Most of the retinal lesions are believed to have followed infection acquired in utero. The rupture of a cyst results in destruction of the bradyzoites if immunity is intact (► [Pathology](#), Fig. 13C); if not, proliferation of tachyzoites results. After either event, retinochoroiditis develops. The release of *T. gondii* antigen is inflammatory in the presence of hypersensitivity, the usual state during chronic infection, and reflected by a positive skin test. In the absence of an effective cellular immunity multiplication of tachyzoite results in destruction of retinal cells and inflammation. Because of the concentration of function in the retina, cyst rupture will often be symptomatic, whereas similarly sized lesions would not be noted in muscle or even the brain. Retinal lesions from recrudescent multiplication of tachyzoites are a dangerous complication of immunosuppression from corticosteroid or tumor chemotherapy, or with AIDS, and if untreated may lead to blindness.

Cerebral Toxoplasmosis

Cerebral toxoplasmosis is seen in immunosuppressed adults such as those treated for Hodgkin's disease, other lymphomas or carcinomas, in corticosteroid-treated patients after organ transplantation, and in patients with AIDS. Encephalitis usually results during chronic infection probably after an accidental cyst rupture. Normally the bradyzoites would be destroyed

with a glial scar remaining (► [Pathology](#), Fig. 5A, B). However, because of the immunosuppression, the released bradyzoites have time to develop into tachyzoites and to multiply, wandering from cell to cell and producing an ever-expanding focus of necrosis accompanied by little inflammation (► [Pathology](#), Fig. 10A, B). One or numerous focal lesions have been found in the brains of immunosuppressed patients. They can be identified by computerized tomography and magnetic resonance imaging where they resemble abscesses, although microscopically they are focal necrosis without granulocytes or pus, the hallmark of an ► [abscess](#).

Immune Responses

Interaction between *T. gondii* and the functional immune system does not result in parasite elimination, but rather in a reduced parasite load and changes in morphology and surface antigen expression. The adapted parasites persist as bradyzoites in cysts located in different tissues for the remaining life span of the host. Acquired immunosuppression leads to reactivation of the parasite resulting in life-threatening toxoplasmic encephalitis. The sexual part of the life cycle of *Toxoplasma* takes place in the intestine of the definitive host, the cat. Despite the sexual life cycle in cats, only three major clonal lineages have been identified with little of the recombination one would expect if these animals fed on prey infected with different *T. gondii* strains. Thus, under normal conditions, the protective immune response against *T. gondii* is effective and long-lasting, thereby preventing infection of animals with multiple strains of *T. gondii*.

Intracellular Survival and Host Cell Activation

T. gondii is able to replicate in nearly all nucleated cells of mammals. The intracellular fate of the parasite depends on the type and activation state of the host cell. Depending on the ability to restrict replication of intracellular toxoplasma, all cell

types analyzed so far can be arranged into three groups. Group A consists of cells that are able to restrict the growth of *Toxoplasma* without prior activation, e.g., human monocytes. Group B, to which the majority of cell types belong, includes cells that restrict the growth of the parasite only after activation with cytokines, e.g., IFN- γ . Microglia cells and macrophages of mice as well as human fibroblasts belong to this group. Cells of group C, such as murine astrocytes and fibroblasts or human EBV-transformed B cells, are unable to restrict the growth of *T. gondii*, even after activation with IFN- γ . Cells of group C might thus function as safe harbor and transport vehicle for the spread of the parasite throughout the body. However, depending on the species of the host, the precise nature and frequency of these C-type cells differ, possibly influencing the susceptibility of the mammal species to *T. gondii* infection.

For example, human astrocytes and fibroblasts were found to restrict toxoplasma growth after activation with cytokines, while these cell types from mice support growth of the parasite even after IFN- γ activation. Thus the more severe illness in mice as compared to humans may in part be a consequence of the high frequency of these type C cells in rodents.

Among the cytokines able to induce antitoxoplasma effector mechanisms IFN- γ appears to be the most potent. TNF was found to enhance the activation by IFN- γ in a synergistic manner in vitro and induces protection of mice in vivo. Likewise, IFN- β and IL-1 were described to stimulate toxoplasma effects in human cells in vitro and induced protection in mice infected with *T. gondii*. The protective effects of cytokines such as IL-2, IL-7, and IL-12 in experimental infections of mice are most likely indirect, caused by an enhanced production of IFN- γ . At least three different antiparasitic effector mechanisms induced by IFN- γ have been defined: (1) production of toxic oxygen radicals, (2) production of ► [nitric oxide](#), and (3) degradation of L-tryptophan.

The role of the oxidative burst in control of toxoplasma growth is still a matter of debate, since many conflicting results have been published.

Free radical scavengers such as catalase and superoxide dismutase have been shown to inhibit toxoplasma growth in human and murine macrophages. Although some investigators reported that toxoplasma infection induces oxidative burst, others have been unable to detect even traces of oxidative burst products in comparable cells. Moreover, *Toxoplasma* tachyzoites are at least in part resistant against the damaging effects of toxic oxygen radicals since they possess reactive radical scavengers. The pathway by which toxoplasma enters a cell determines the fate of the parasite. While antibody-coated toxoplasma were rapidly killed in human granulocytes by strong superoxide anion production, parasites without antibodies on their surface were able to replicate and induce only a minor oxidative burst. Thus, toxic oxygen radicals may be operative under certain circumstances, while other mechanisms of defense are definitively also able to inhibit *T. gondii*, even in oxidatively incompetent cells of patients with chronic granulomatous disease.

Nitrogen intermediates such as ► [nitric oxide](#) (NO) contribute to antimicrobial activity of rodent macrophages. The inducible form of NO synthase (iNOS) is induced by IFN- γ and there is no doubt that NO production is the key defense mechanism against *Toxoplasma* (as well as other intracellular pathogens) in murine macrophages and other rodent non professional APCs. In addition, human astrocytes stimulated with IL-1 and IFN- γ are also able to inhibit toxoplasma growth by producing NO. However, as shown by experiments with iNOS inhibitors, NO does not contribute to the defense of human monocyte-derived macrophages against *Toxoplasma*. In addition an IL-12-mediated mechanism of protection independent of iNOS has been recently described in IRF-1-deficient mice infected with *T. gondii*. Although macrophages isolated from iNOS-deficient mice (iNOS $-/-$) displayed defective microbicidal activity against the *Toxoplasma* in vitro, iNOS-deficient mice survived acute infection and controlled parasite growth at the site of infection. By 3–4 weeks p.i., however, iNOS-deficient mice did succumb to *T. gondii* and enhanced

parasite expansion and pathology were evident in the CNS. This suggests that the protective effects of NO might be tissue and/or infection phase-specific.

In many different human cell types IFN- γ induces the indolamine 2,3-dioxygenase (IDO), an enzyme capable of degrading tryptophan. Since tryptophan is an essential amino acid for *T. gondii*, the depletion of this amino acid results in parasite growth inhibition. This has been confirmed by several different experimental findings, e.g., (1) the fact that tryptophan supplementation partly antagonized antiparasitic effects induced by IFN- γ in human cells (2) the absence of antiparasitic effector mechanisms in a mutant cell line lacking the IDO gene, and (3) the capability of tryptophan gene-transfected *T. gondii*, which are no longer tryptophan auxotroph, to replicate in human IFN- γ treated fibroblasts. The induction of IDO appears to be inhibited by NO in rodent cells, since the addition of iNOS inhibitors resulted in detectable IDO activity in stimulated murine macrophages.

The existence of further defense mechanisms in addition to oxidative burst, NO production and tryptophan degradation is suggested by experiments in which the inhibition of all three pathways in human endothelial cells did not abolish the IFN- γ -induced antiparasitic effect.

Innate Immunity

Mice deficient in the gene for MyD88, an adaptor molecule essential for most TLR as well as IL-1 and IL-18 signaling, were shown to have defective IL-12 responses during parasite infection and, in the case of *T. gondii*, were acutely susceptible to the pathogen. In a subsequent elegant study Yarovsky et al. identified a profilin-like protein from *T. gondii* that generates a potent IL-12 response in murine dendritic cells (DCs). *T. gondii* profilin activates DCs through TLR11 and is the first chemically defined ligand for this TLR. Moreover, TLR11 is required in vivo for parasite-induced IL-12 production and optimal resistance to infection. In addition glycosylphosphatidylinositol (GPI) protein anchors are highly

abundant in the membranes of *T. gondii* tachyzoites and can serve as ligands for innate recognition through TLR2 as well as TLR4 agonists. TLR2-deficient mice display enhanced susceptibility when challenged with high infective doses of *T. gondii*. A role for TLR2 is also suggested by the requirement for this receptor in the *T. gondii*-induced production of the neutrophil-attracting chemokine CCL2 both in vitro and in vivo. The latter observation is relevant because of the known involvement of neutrophils in the innate response to the parasite. An increased percentage of neutrophils has been detected in the blood of mice infected with *T. gondii* by gavage and depletion of neutrophils by specific antibodies resulted in increased disease-severity and death during acute toxoplasmosis. Another cell type possibly contributing to the very early innate defense against *T. gondii* are platelets. It was observed that tachyzoites of *T. gondii* induced activation of human platelets and that platelet-derived growth factor inhibited intracellular growth of the parasite.

In experimental infection of mice, one of the first events occurring after infection with *T. gondii* is the activation of NK cells. However, in contrast to human IL-2-activated NK cells, murine NK cells are unable to lyse *T. gondii*-infected target cells. Instead, IFN- γ produced by mouse NK cells appears to be of importance for early resistance against *T. gondii*. Although T cell-deficient SCID mice eventually succumb to infection, IFN- γ produced by NK cells leads to control of the parasite soon after infection. In addition, administration of IL-12 to SCID mice known to stimulate NK cells resulted in a remarkable delay in time till death, while treatment with anti-IL-12 resulted in early ► **lethality** following infection. Antigen preparations of *T. gondii* can activate NK cells in vivo and in vitro, presumably via stimulation of the secretion of monokines such as IL-1, IL-12, and TNF by macrophages or as shown recently for IL-12, by dendritic cells. In addition to these NK-stimulatory cytokines, cell-cell contact involving CD28 on NK cells and CD80 or CD86 on macrophages is able to amplify the IL-12-driven IFN- γ production of NK cells. Only in the absence of a functional NK compartment as

seen in mice deficient for the common γ -chain of cytokine receptors, are $CD4^+$ cells able to confer early IFN- γ -dependent resistance.

The fall of NK cell activity shortly after the initial peak of activation appears to be mediated by IL-10 and TGF- β . Following infection with *T. gondii*, the expression of both of these cytokines is upregulated and treatment of SCID mice with neutralizing antibodies against IL-10 or TGF- β delays the time period till death.

B Cells and Antibodies

An important immune reaction of mammalian hosts is the production of IgM and IgG antibodies directed against *T. gondii*, which eventually activate complement by the classical pathway, resulting in efficient killing of extracellular parasites. In contrast, activation of complement by the alternative pathway, does not result in destruction of *T. gondii*. A protective role of IgA is suggested by the finding that secretory IgA obtained from toxoplasma-infected cats reduced the parasite's cell penetrating activity. The humoral immune response is mainly involved in the acute phase of *T. gondii* infection, possibly hampering hematogenous spread of extracellular tachyzoites.

T Cells

In addition to NK cells, T cells driven by a recently described superantigen of *T. gondii* play an important role after infection with the parasite. This manifests as expansion of $CD8^+ V\alpha 5^+$ cells producing IFN- γ soon after infection followed by nonresponsiveness of this population during chronic infection. Surprisingly and for reasons unclear at the moment, mice expressing the highest levels of $V\alpha 5^+$ cells display also the highest mortality level. IL-12 and IFN- β expressed during the early response play a decisive role in the development of Th1 cells, which in turn produce IL-2 thereby driving the expansion of $CD8^+$ cells. Adoptive transfer and in vivo depletion experiments in various mouse strains

confirmed the paramount importance of $CD8^+$ T cells in controlling the acute infection as well as in preventing toxoplasmic encephalitis. $CD8^+$ cells mediate their protective effects through three different mechanisms: (1) production of IFN- γ important for the activation of macrophages, (2) MHC class I restricted cytotoxicity for *Toxoplasma*-infected cells, and (3) direct tachyzoite cytolytic activity. Perforin-mediated cytotoxicity by T and NK cells, however, plays a limited role in host resistance to *T. gondii*, since *T. gondii*-vaccinated perforin-deficient mice were completely resistant to a challenge infection and only in the chronic stage of toxoplasmosis was there a three- to fourfold enhancement of brain cyst numbers in the mice lacking perforin.

The role of $CD4^+$ T cells during *T. gondii* infection remains controversial. On the one hand depletion of $CD4^+$ cells in vivo exacerbated the course of the disease, increased parasite burden and promoted recrudescence of latent infection. On the other hand, $CD4^+$ cell depletion reduced brain inflammation and Th1 cells were associated with the development of necrotic lesions in the ilea of susceptible mice. In contrast, the coproduction of Th2 cytokines together with IFN- γ by $CD8^+$ cells in the gut-associated lymphoid tissue ([► GALT](#)) may be essential to limit the pathological inflammatory response.

Given the decisive role of T cell for the immune defense against *T. gondii*, it is important to mention, that infection of murine macrophages with the parasite results in downregulation of MHC class II molecules and inability to upregulate class I molecules. The interference with antigen presentation may be an [► evasion](#) strategy of *T. gondii* to facilitate intracellular survival.

In addition to the activation of T cells expressing $\alpha\beta$ TCRs, an activation of $\gamma\delta^+$ T cells has been described in humans as well as in mice. These cells were found to play a role in the induction of hsp 65 expression of macrophages and were mainly involved in the early defense against *T. gondii* in the gut by mechanisms which await clarification.

Toxoplasma Immunity in the Brain

In the course of toxoplasmosis the central nervous system is almost always involved. The limited access of cells of the immune system to the brain may, in part, explain the persistence of the cyst stage in the brain which is responsible for the neurological symptoms in congenital toxoplasmosis and reactivation *Toxoplasma*-encephalitis in immunocompromised individuals.

The unique immune status of the brain is a consequence of a number of factors. Resting T cells, antibodies, and cytokines are unable to cross the blood-brain barrier, and a primary immune response does not usually occur. In addition, glial cells are known to be able to suppress T cell responses. Since furthermore the CNS lacks a proper lymphatic system and only low levels of endogenous MHC class I and II molecules are expressed, it may be easy for *T. gondii* to evade the full consequences of the host immune system at this site.

Although *Toxoplasma*-encephalitis is one of the most common manifestations of clinical toxoplasmosis there clearly is evidence for antiparasitic effector mechanisms operative in the brain. The essential role of T cells is illustrated by the fact that there is no toxoplasmic encephalitis in immunocompetent individuals, while the disease occurring in AIDS patients is almost invariably associated with very low CD4⁺ T-cell counts (<100/mm³) with a corresponding reduction in CD8⁺ T cells. In addition to the impaired T-cell function in AIDS patients, macrophages infected with HIV have a reduced ability to kill *T. gondii*. Furthermore, a direct link between replication of *T. gondii* and HIV is suggested by the fact that *T. gondii* infection of HIV-1-transgenic mice stimulated proviral transcription in macrophages. Thus, infection with *T. gondii* might increase the viral replication, thereby hastening the loss of T cells and allowing *Toxoplasma*-encephalitis to develop.

In murine *Toxoplasma*-encephalitis adult immunocompetent mice were found to develop cellular infiltrates composed of CD4⁺ and CD8⁺

T cells and macrophages surrounding *Toxoplasma* cysts and tachyzoites. Cell transfer experiments showed that especially CD4⁺ T cells are able to confer protection against cyst reactivation in the brains of infected SCID mice. In addition, it was found by cell depletion experiments that CD8⁺ T cells participate in the control of cyst numbers.

Analysis of cytokine production in the brains of *T. gondii*-infected mice indicated that the outcome of the encephalitis is dependent on the differential production of Th1 or Th2 cytokines. IFN- γ appears to be the most important protective cytokine since (1) administration of rIFN- γ to chronically infected mice reduced disease severity which (2) was enhanced in mice treated with neutralizing antibodies against this cytokine and (3) IFN- γ receptor-deficient mice with a resistant genetic 129 background rapidly died following infection. Studies showing that administration of the NO inhibitor aminoguanidine resulted in increased severity of *Toxoplasma*-encephalitis strongly suggest that NO synthesis is an important mechanism of IFN- γ -induced protection. TNF is another cytokine which appears to be centrally involved in the control of *Toxoplasma*-encephalitis since treatment with TNF-neutralizing antibodies or the disruption of the TNF receptor p55 gene resulted in increased disease severity. In line with these findings, the enhanced *T. gondii*-resistance of male mice compared to females is associated with more rapid production of IL-12, IFN- γ and TNF.

The role of other cytokines is less clear. IL-6 neutralization using antibodies in mice with established encephalitis led to reduced brain inflammation and decreased parasite burden, while IL-6-deficient mice were found to be more susceptible than their immunocompetent counterparts. The function of the Th₂ cytokines IL-4 and IL-10 is also uncertain. Elevated levels of expression of both these cytokines have been detected in brains of mice with *Toxoplasma*-encephalitis. While studies with mice deficient in IL-4 or IL-10 demonstrated an enhanced disease susceptibility others reported that IL-4 deficient mice were resistant to *Toxoplasma*-encephalitis. The

differences between these studies may be related to the different strains of parasites and genetic backgrounds of the mice.

Immune Pathogenesis

T. gondii infection during both the acute and the chronic phases of disease is controlled by a delicate balance between different inflammatory and regulatory cytokines. As described above, the production of IL-12, IFN- γ and TNF is a prerequisite for protective immunity, but on the other hand their overproduction can also be deleterious to the host. For example, mouse strains producing the highest levels of IFN- γ also have the highest mortality rates. In addition, administration of rTNF results in earlier mortality in immunocompetent and SCID mice. In addition, mice lacking IL-10, a counter regulator of cell-mediated immunity, are more susceptible to toxoplasmosis.

Vaccination

T. gondii is one of the most successful parasites able to infect virtually all nucleated cells from a broad host-range including birds, farm animals, wild animals, and humans. Moreover this parasite is easy to grow, is haploid in most stages, and can easily be manipulated by transfection strategies. Although there is no evidence of sophisticated mechanisms such as ► [antigenic variation](#), the parasite has developed a strategy to infect the host cells allowing to escape to the immune system and/or trigger different immune effectors. It has been shown that the parasitophorous vacuole formed upon penetration of tachyzoites into macrophages, or fibroblasts is fusion-incompetent. This would allow the parasite to avoid direct cellular destruction by macrophage machinery. Nevertheless, like a number of other intracellular pathogens, such as ► [Leishmania](#), macrophages activated by cytokines, notably those derived from activated T cells, acquire the capacity to kill or inhibit the development of intracellular

pathogens. In vitro studies as well as experiments in *Toxoplasma*-infected mice whose cytokine genes or cytokine receptor genes have been inactivated have shown that IFN- γ and TNF- α are the most cytokine implicated. The general consensus is that *T. gondii* induces TNF- α and IL-12 production by macrophages. This induces IFN- γ release by NK cells that synergize with TNF- α for the parasite killing by a combination of oxygen-dependent and independent mechanisms. Intracellular macrophage killing cannot be sufficient to account for the immune control of the infection since *Toxoplasma* (in contrast with *Leishmania* parasites) is able to develop in practically every nucleated cell. Although the role of T cells in anti-*Toxoplasma* immunity has been recognized for a long time, it is only recently that important progress has been made in understanding the control mechanisms involved, particularly the role of CD8⁺ T cells. CD8⁺ would have not only a direct tachyzoite cytolytic activity but also would prevent high cysts burden and *Toxoplasma*-encephalitis through IFN- γ secretion. Although cell-mediated immunity is the major component, antibodies also have been protective in models. While antibodies do not seem to play an essential role in maintaining a steady-state equilibrium between the parasite and the host during the chronic phase of the infection, they could participate in the protection during the primary infection in vaccinated animals.

A vaccine comprising live attenuated tachyzoites (the infecting stage) is already successfully used in sheep to prevent abortion, but such vaccine is inappropriate in humans. Therefore an important research area is the identification of molecules involved in the invasion process by the tachyzoite of the parasite in its host cell. It is a difficult issue because the parasite has evolved a complex family of redundant receptors able to match to virtually all nucleated cells within an enormous number of animals from birds to humans. The new advances of the reverse genetics have made it possible to clarify the respective roles of the tachyzoite surface antigens in the invasion process and therefore has pointed out

some of these antigens as interesting targets for vaccine development. Among the five originally described surface antigens three have been extensively studied: SAG1 (P30), SAG2 (P22), and SAG3 (P43). SAG1 and SAG3 correspond to homologous proteins with 24 % of amino-acid identity and conserved cysteines leading to similar secondary and tertiary structures. SAG2 shows no apparent similarities with SAG1 and SAG3, other than that these three tachyzoites are anchored in the membrane by glycosylphosphatidyl inositol (► [GPI](#)) moieties. Polymorphism analysis of these antigens has shown that in contrast to what is observed for *Plasmodium* merozoite antigens (MSP1 and MSP2 for instance), the number of allele is extremely limited which is encouraging for vaccine development. For instance, the analysis of the SAG1 locus (encoding the P30 surface antigen) has shown the existence of only three alleles, two of them (CEP and ME49) encoding for identical proteins and two alleles have been described for SAG2. Vaccination experiments using one or the other of these two antigens, SAG1 and SAG2, as recombinant antigens or synthetic peptide have given drastically different results, reducing or increasing the mice or rats mortality, depending on the adjuvant. Indeed recent knowledge on immune responses against *T. gondii* have readily established that induction of CD8⁺ T cells and Th1 cells is pivotal for the induction of a successful control of *T. gondii* infection. Adjuvant inducing a Th1 response such as immunostimulatory complexes (ISCOMs) induce generally protecting immunity whereas adjuvant promoting Th2 responses such as Aluminium hydroxyde (the only adjuvant licenced for use in humans) exacerbate the disease in rodent models. Recombinant cytokines such as IL-12, that is determinant for Th1 differentiation, could provide the adjuvant activity for new generation vaccine as proven by successful experiment for *Leishmania* vaccination. However the surproduction of pro-inflammatory cytokines, such as IFN- γ and TNF- α , may increase ► [morbidity](#) or/and

mortality. Indeed, recent elegant experiments have found a correlation between the susceptibility of inbred mouse strains to *Toxoplasma* encephalopathy (TE) and the structure of the gene to TNF α . Thus, differences in TNF α expression could be one of the factors implicated in the TE susceptibility.

In contrast to SAG3 which is expressed on tachy- and bradyzoites surface, SAG1 and SAG2 are abundant tachyzoite specific antigens, highly immunogenic. Mutant parasites lacking either SAG1 or SAG3 clearly show an impaired invasion, suggesting a role in the attachment of the parasite to the host cell. SAG2 would rather play a role in the reorientation of the tachyzoite during the invasion process as indicated by blocking experiments with mabs against SAG2. Invasion and establishment in the parasitophorus vacuole is a key event for the survival of this parasite. The GRA proteins, discharged from the dense granule play a major role in the modification of the parasitophorus vacuole, and may also be relevant as vaccine component. Immunization of mice with GRA2 induces the increase of the survival of mice from 10 % to 75 %. Recent advance in the *Toxoplasma* genome project has yielded over 10,000 expressed sequence tags (ESTs) from *Toxoplasma gondii*. Sequencing of ESTs has already lead to the discovery of four new SRS genes (SAG1 Related Sequences), increasing the ► [SAG](#) family to eight members. As SRS antigens are less abundant antigens they were missed by classical biochemical techniques. This illustrated the fantastic potential advance coming from the postgenome period in the discovery of new vaccine candidates. Due to the stage specificity of *Toxoplasma* antigens as well as the differential immunological control of the tachy- and bradyzoite stages, an efficient vaccine preventing fetal damages and abortion as well as reducing cysts formation has to contain multistage antigens. Thus future vaccine research has not only to target antigens from different stages but also to induce the appropriate immune responses. Further progress in the dissection of protective defense

mechanisms in experimental models as well as naturally infected individuals will help for vaccine design.

Once established in host cells and disseminated, *T. gondii* differentiates from tachyzoites to the persistent encysted bradyzoite stages. Knowledge about factors which lead to bradyzoite, or oocyst formation is still very poor and almost nothing is known about the genes which are involved in this transition. Concerning cysts wall composition, Sims et al. have recently reported the presence of *Toxoplasma* antigens, but the interaction between these antigens and the host immune system has not yet been investigated. The understanding of the mechanisms by which this stage becomes reactivated in immunocompromised host, is a major challenge for researchers, in order to develop strategies preventing this transition. Decreasing levels of IFN- γ observed in AIDS patients would play a role via the decrease of expression of indoleamine 2,3-dioxygenase (IDO) and inducible NO synthase (iNOS), which are important for the stabilization of the cyst stage. New approaches in molecular genetics, cellular microbiology, and immunology will clarify the complex interrelationship between the different forms (tachyzoites, bradyzoites, and oocysts) as well as the suitable balance in the induction of immune mechanisms, knowledge essential for vaccine development.

Lastly, recent experiments have highlighted the possibility of expressing *P. falciparum* antigens in *T. gondii* opening the possibility of using *T. gondii* as carrier for vaccination.

Main clinical symptoms: In immunoincompetent people mostly symptomless, but in acute infection the following are common: lymphadenitis, iridozyklitis, chorioretinitis, myocarditis, meningoencephalitis-mylitis; see ► [Connatal Toxoplasmosis](#).

Incubation period: Hours to 2 days.

Prepatent period: 1 day to weeks (strain-dependent).

Patent period: Years.

Diagnosis: Serodiagnostic tests, ► [Serology](#).

Prophylaxis: Avoid eating raw meat and having contact with cats that feed on mice.

Therapy: see ► [Treatment of Opportunistic Agents](#), ► [Coccidiocidal Drugs](#).

Toxorhynchites brevipalpis

► [Diptera](#), mosquito species, that does not suck blood.

Traberkrankheit

German common name for a disease of small ruminants due to an infection with the agents of scrapie disease (► [Prions](#)). Scrapie initiates (like the worm-derived ► [turning disease](#) or ► [whirling disease](#)) uncontrolled movements due to disintegration of the brain.

Trachea

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Latin: *trachys* = rough.

The vessel leading oxygen from mouth to lungs.

Tracheoles

Chitin-fortified hollow tubes, which start at the surface of insects/acarids (at stigmata) and are used as channels for O₂ supply leading to the single cell.

Tracheophilus sisowi

Cosmopolitan digenean trematode (6–11.5 mm × 3 mm), that parasitizes in the pharynx, nasal region, and bronchioles of house and wild birds. Intermediate hosts are snails (*Lymnaea*, *Planorbis*, *Planorbarius*).

Trachoma

About 540 million humans in 55 countries (primarily in Africa, Asia, but also in regions of the Americas and Australia) are endangered to become infected by the fly-transmitted bacterium *Chlamydia trachomatis*. The disease may lead via severe symptoms (e.g., conjunctivitis, trichiasis) to blindness, which, however, is preventable by the use of proper means of control (e.g., use of Azithromycin), ► [eye parasites](#).

Transfection

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This method covers the introduction of foreign DNA (e.g., reporter genes) into a cell. This transfection is often transient, since the segregation of this DNA is not selected for and therefore becomes not carried through mitosis/meiosis. As a consequence the number of cells containing that introduced DNA diminishes within a limited period (= transient infection). In stable infections foreign DNA is integrated into a cell either as an episome or directly into the chromosomal DNA.

Transferrin

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes an iron-binding protein being located in the blood plasma of hosts regulating the level of free iron. This protein is endocytosed by ► [Trypanosoma brucei](#) and other species via transferring receptors in the flagellar pocket.

Transformation

Bite-transmitted parasites (e.g., *Plasmodium*, *Trypanosoma*, *Leishmania*) must adapt to the environment inside of the vector and after transformation again in a similar process, to the vertebrate host (to achieve the metacyclic stage that is able to survive), ► [Phlebotomus](#), ► [Leishmania](#).

Transforming Growth Factor β

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This pleiotropic anti-inflammatory cytokine suppresses T-helper cells.

Transforming Growth Factors (TGF)

Factors (β-type) that lead to stage conversion in many parasites (African trypanosomiasis, cryptosporidiosis, *Plasmodium* spp., etc.).

Transmission

Parasites may become transmitted to their hosts by

- Fecally contaminated food or drinking water,
- Raw or undercooked meat of fish or animals,
- Milk,
- Body fluids (including mothermilk),
- Bite of ectoparasites,
- Active penetration into the skin,
- Body contact between two hosts,
- Air-borne inhalation

Transmission Peculiarities

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The protozoan flagellates ► *Dientamoeba fragilis* and ► *Histomonas meleagridis* were considered for long to be transmitted from host to host in a very peculiar way. It was claimed first by the parasitological authority Dobell (1940) that *Dientamoeba fragilis* is transmitted inside the eggs of pinworms (► *Enterobius vermicularis*) and that *Histomonas meleagridis* might be similarly transmitted by eggs of *Heterakis gallinae*. This pathway would implicate that female worms inside the intestines of their hosts ingest the tiny smoothly limited trophozoites of *D. fragilis* and *H. meleagridis*, which finally are included into the eggs. This is rather problematic, since there is a robust wall around the worm's uterus. But on the other side, DNA of *D. fragilis* was found in the eggs of *Enterobius vermicularis* (Ögren et al. 2013). On the other side, cysts had been shown in *Histomonas meleagridis* (Munsch et al. 2009; Zaragatzki et al. 2010; Hauck and Hafez 2013). Thus it might be concluded that

this cyst transmission is the main pathway. This is supported by several studies, where no relations were found between pinworms and the flagellates (Barratt et al. 2011) in hosts, which were clearly infected by *D. fragilis* or *H. meleagridis*.

Transovarial Transmission

Some agents of diseases enter the eggs of insects or ticks and thus become transmitted to the next generation. For example, ► *Babesia*, viruses (meningitis), etc., ► *Borrelia burgdorferi*.

Transsialidase Transmission

Trypanosomes are unable to synthesize the monosaccharide sialic acid and thus incorporate it from the host. In order to do so, e.g., *T. cruzi* expresses a transsialidase that catalyzes the transfer of sialic acid from host glycoconjugates to mucin-like molecules on the parasites' membrane.

Trans-Splicing

W. F. Martin

Institut für Molekulare Evolution, Heinrich-Heine-Universität, Düsseldorf, Germany

Trans-splicing is a mechanism of nuclear pre-mRNA maturation that occurs in several branches of eukaryotes, including kinetoplastids, euglenoids, ► [nematodes](#), ► [flatworms](#), and primitive chordates, but does not exist in vertebrates. *Trans*-splicing appears to reflect an ancestral form of RNA processing that is used to donate a leader sequence (► [Spliced Leader](#), SL) from the 5' end of a small mRNA (SL RNA) to pre-mRNAs to form the 5' end of the mature mRNAs (Fig. 1). The fundamental mechanism of *trans*-splicing parallels that of *cis*-splicing in higher eukaryotes.

Trans-Splicing, Fig. 1 Schematic illustration of the proposed reactions involved in the *trans*-splicing of kinetoplastids, ► [trematodes](#), and nematodes. BS branching site, SL ► [spliced leader](#), SS splice sites

One major difference between the two events is that *trans*-splicing involves the joining of exons from two separately transcribed RNAs, while *cis*-splicing mediates the removal of intervening sequences in eukaryotic pre-mRNAs. Both splicing processes take place in one of the most complex macromolecular machines known as the spliceosome. In trypanosomatids, virtually all pre-mRNAs receive the SL and *cis*-splicing is confined to a very few pre-mRNAs, whereas in helminths only a part of the pre-mRNAs is processed by *trans*-splicing. *Trans*-splicing has several distinct biological functions. A unique role in kinetoplastids is that it provides a 5' cap structure for mRNAs transcribed by RNA polymerase I, and in the same organisms, flatworms, and nematodes, it serves to resolve polycistronic RNA polymerase II transcripts into capped, monocistronic mRNAs.

Transstadial Transmission

Transmission of sporozoites via saliva in ► [Theileria](#), after their formation in the salivary glands of ticks.

TRAP

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The thrombospondin-related anonymous protein (TRAP) of ► [Plasmodium](#) species is an important partner for sporozoites during their invasion into the liver cell by linking to actin via its cytoplasmic tail and while binding to the hepatocytes via its extracellular portion.

Further Reading

Morahan BJ et al (2009) No TRAP, no invasion. Trends Parasitol 25:77–84

Traps

Insects have to be caught in order to determine their parasitic load. The attraction of traps is initiated by light (UV, black light), or by chemicals, or by pheromones.

Traumatic Insemination

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Description of the way, how male bed bugs inject sperms into the body cavity of the females. In principle they try to reach the so-called ► [Ribaga](#) organ below the body cover, but mostly they inject their insemination organ (► [aedeagus](#)) just into the body cavity of the female.

Traveller's Disease

Disease due to infections with ► [Cyclospora cayetanensis](#); the leading symptom is diarrhea, which may also occur in infections with *Blastocystis*, *Giardia*, ► [microsporidia](#), *Entamoeba*.

Travellers Information

JAMA: <http://www.jama.com>.

Treatment

See chapters on “Disease Control” and “► [Control](#).”

Treatment of Opportunistic Agents

Wolfgang Raether¹ and Achim Harder²

¹Hoechst, Frankfurt, Germany

²Bayer HealthCare AG, Division Animal Health, Leverkusen, Germany

Pneumocystis carinii, a unicellular eukaryote (a fungus), develops extracellularly in the alveoli of lungs of animals (e.g., rat) and humans (a particular species *P. jiroveci* (a new name) that does not infect other host species) thereby undergoing encystment during one phase of its life cycle (► [Pneumocystis carinii](#)). The **clinical symptoms** of acute pneumonitis in immunosuppressed children and adults, both, with and without HIV infection are dyspnoea, tachypnoea, cough, and fever. In immunocompetent hosts the infection is latent without any clinical signs and widely distributed in a variety of domestic and wild animals. Direct or close contact to carriers, and airborne transmission seems to be the common route of infection in humans. The incidence rate is high and may exceed 80 % in children. An effective **therapy** of infection with chemotherapeutic drugs (cf. Table 1) is dependent on early diagnosis. Treatment of choice for PCP and extrapulmonary *Pneumocystis* infections in ► [AIDS](#) patients is oral (PO) or intravenous (IV) administration of trimethoprim plus sulfamethoxazole (Bactrim and others). The dosage is 15 mg/kg b.w./day (based on trimethoprim component) given in three or four doses × 14–21 days. In PCP accompanied by severe hypoxia, oral prednisone at the start of treatment has decreased incidence of respiratory deterioration and may improve tolerance for high-dose trimethoprim + sulfamethoxazole. However, the corticosteroid may reactivate herpes simplex infections

Treatment of Opportunistic Agents, Table 1 Drugs acting on opportunistic infections among HIV-exposed or infected humans

DISEASE non-proprietary name (chemical group)	Adult dosage/*pediatric dosage (mg/kg b.w., or total dose/individual, oral route), miscellaneous comments
Brand name other information	
PNEUMOCYSTOSIS (<i>Pneumocystis pneumonia</i> = PCP) is an acute, usually a bilateral and diffuse pneumonitis caused by pulmonary infection of <i>P. carinii</i>; this unicellular eukaryote that usually develops extracellularly in the lungs of rats undergoes encystment in one phase of its life cycle; its biological characteristics resemble those of both fungi and the protozoans; <i>Pneumocystis</i> organisms are quite different on the basis of DNA analysis in different mammals and widely distributed in nature; in immunocompetent hosts, the infections are latent and asymptomatic; <i>P. jiroveci</i> is an important pathogen causing opportunistic pneumonia in immunosuppressed humans; PCP remains the most common AIDS-indicator disease among HIV-infected children (>60 % of AIDS patients in the USA and Europe were estimated to develop PCP); extrapulmonary infected lesions (all tissues) are more common in AIDS patients than in other immunocompromized persons; prevention of PCP and its treatment is entirely dependent on current chemotherapeutic drugs, which all may produce severe side effects; early diagnosis is essential for effective treatment consisting of both specific chemotherapy and supporting therapy; chemoprophylaxis against PCP is necessary for individuals suffering from conditions such as AIDS, aids related complex (ARC), acute lymphoblastic leukaemia, and those having received solid organ transplants or bone marrow transmission; aerosolised pentamidine (AP) given by inhalation is extensively used for PCP prophylaxis in children >6-year old and adults producing moderate to severe cough as adverse effect; undesirable side effects may require termination of AP but this may also be true for all other treatment regimens used to prevent PCP; in PCP, accompanied by moderate or severe hypoxia, adding prednisone (corticosteroid) at the start of treatment has decreased the incidence of respiratory deterioration and death; corticosteroids may also improve tolerance for high-dose trimethoprim-sulfamethoxazole; oral candidiasis and reactivation of herpes simplex infections can occur; at present no protective vaccine against PCP is available	
Trimethoprim (TMP)/sulfamethoxazole (SMX) (diaminopyrimidine/sulfonamide) Bactrim, eusaprim, and others (drug of choice) recommended therapy, after acute pneumonitis has resolved patient can be administered oral treatment	TMP 15 mg/kg/day, SMX 75 mg/kg/d (i.v. or p.o. = per os) in 3 or 4 doses $\times$ 14–21 day; *same as adult dose; adverse effects may be folate deficiency, neutropenia, thrombocytopenia, agranulocytosis, rash, fever, headache, depression, jaundice, diarrhoea (rare) and others; is the treatment of choice for PCP and extrapulmonary <i>P. carinii</i> infections; episodes of toxicity may require discontinuation of the drug; subsequent desensitisation may lead to renewed drug tolerance
Pentamidine isetionate (aromatic diamidine) Pentam, others (<i>alternative therapy</i>) it is recommended for patients intolerant of TMP/SMX or who demonstrate clinical treatment failure after 5–7 days of TMX/SMX therapy	3–4 mg/kg i.v. (over 60–90 min.) qd $\times$ 14–21 day; *same as adult dose; side effects may be sharp fall in blood pressure after rapid i.v. injection (orthostatic hypotension); it can induce pancreatitis (hypoglycemia and hyperglycemia), reversible renal dysfunction, abortion, peripheral neuritis (rare), cardiac arrhythmias; drug is contraindicated in diabetes
Trimetrexate plus folinic acid (diaminopyrimidine) Neutrexin, others (<i>alternative therapy</i>) has been used as initial therapy in severe PCP in adults; data are limited for children	45 mg/m² i.v. qd $\times$ 21 day plus folinic acid 20 mg/m² p.o. or i.v. q6h $\times$ 21 day; antifolate drug approved for treatment of moderate to severe PCP; is not as effective as TMP/SMX; folinic acid (e.g., Leucovorin) prevents bone marrow suppression; (Neutrexin is licensed in the USA and elsewhere)
Trimethoprim plus dapsone (diaminopyrimidine/sulfone) (<i>alternative therapy</i>) pediatric dose of TMP is the same as adult dose; among children aged <13 years a dapsone dose of 2 mg/kg/day is required to achieve therapeutic levels	5 mg/kg TMP p.o. tid $\times$ 21 day plus dapsone 100 mg per os qd $\times$ 21 day; antileprosy sulfone dapsone given concurrently with trimethoprim can be used in treatment of mild to moderate PCP; adverse effects may be nausea, rash and methaemoglobinemia and haemolytic anaemia in patients with G-6-PD deficiency; (drugs are not licensed for this dosage regimen in the USA but considered investigational for this condition by the FDA)

(continued)

Treatment of Opportunistic Agents, Table 1 (continued)

DISEASE non-proprietary name (chemical group)	Adult dosage/*pediatric dosage (mg/kg b.w., or total dose/individual, oral route), miscellaneous comments
Brand name other information	
Atovaquone (ATQ) (hydroxynaphthoquinone) Mepron, others (suspension) (<i>alternative therapy</i>) pediatric dose: 1–3 months: 30 mg/kg/day; 4–24 months: 45 mg/kg/day >24 months: 30 mg/day ATQ concentration is increased/decreased with coadministration of fluconazole and prednisone/acyclovir, opiates, cephalosporins rifampin and benzodiazepines	750 mg bid p.o. × 21 day; can be used for treatment of mild to moderate PCP; it is less effective than TMP/SMX but better tolerated; most side effects may be nausea, skin rashes and diarrhea after first week of therapy (licensed in the USA and Europe)
Primaquine phosphate (PMQ) (8-aminoquinoline) plus clindamycin (CDM) (7-chloro-lincomycin) (alternative therapy) Cleocin, and others dose information (data) for children is limited and based on use of these drugs for treatment of other infections, e.g., bacterial ones: 10 mg/kg q6h CDM, or malaria: 0.3 mg/kg q6h PMQ; adverse reactions include skin rashes, nausea, and diarrhea	30 mg base p.o. qd × 21 day plus clindamycin 600 mg i.v. q6h × 21 day, or 300–450 mg p.o. q6h × 21 day; concurrent use of i.v. or oral clindamycin with oral primaquine can be used in patients with mild to moderate PCP; <i>primaquine</i> can frequently cause haemolytic anaemia, especially in patients whose red cells are deficient in glucose-6-phosphate dehydrogenase, this deficiency is most common in African, Asian and Mediterranean peoples; patients should be screened for G-6-PD deficiency before treatment, it should not be used during pregnancy; (not licensed in the USA but considered investigational for this condition by the FDA)
Primary and secondary prophylaxis: in HIV-infected patients, <i>Pneumocystis pneumonia</i> can be prevented by oral TMP/SMX or other alternative drugs; chemoprophylaxis in patients with HIV can be discontinued after CD4 count increases to $>200 \times 10^6/L$ for >3 months	
Trimethoprim /sulfamethoxazole (TMP/SMX) (diaminopyrimidine/sulfonamide) Bactrim, and others (drug of choice) an alternative TMP/SMX regimen is one DS tab 3×/week; weekly therapy with <i>sulfadoxine</i> 500 mg/ <i>pyrimethamine</i> 25 mg/folinic acid 25 mg was effective PCP prophylaxis in liver transplant patients	1 tablet (single or double strength/=DS) p.o. qd daily; *TMP 150 mg/m ² , SMX 750 mg/m ² in 2 doses p.o. on 3 three consecutive days per week; oral TMP/SMX prophylaxis can prevent PCP in most HIV-infected patients; adverse reactions are frequent, particularly nausea, rash and fever; reduction of dosage may reduce toxic episodes or patients have to discontinue the drug and take an alternative drug
Dapsone (sulfone) (not licensed in the USA but considered investigational for this condition by the FDA) (alternative drug)	50 mg p.o. bid or 100 mg p.o. qd; *2 mg/kg (max. 100 mg) p.o. qd or 4 mg/kg (max. 200 mg) each week; frequent rash, GI irritation, anorexia, infectious mononucleosis-like syndrome, occasionally methaemoglobinemia, haemolytic anaemia (G-6-PD deficiency), nephrotic syndrome, liver damage and others, rare optic atrophy, agranulocytosis
Dapsone (sulfone) plus pyrimethamine (PYR) (diaminopyrimidine) plus folinic acid (alternative drugs)	50 mg p.o. qd or 200 mg each week plus pyrimethamine 50 mg or 75 mg p.o. each week plus 25 mg folinic acid with each dose of PYR; PYR occasionally causes blood dyscrasias, folic acid deficiency, rare rash, and vomiting
Atovaquone (hydroxynaphthoquinone) Mepron, others (alternative drug) for interaction with other drugs cf. atovaquone↑	750 mg bid; frequent rash, nausea, occasionally diarrhoea; (licensed in the USA and elsewhere); antimalarial drug in combination with proguanil (Malarone, GSK, cf. ► Malariacidal Drugs)
Pentamidine aerosol (diaminopyrimidine) Nebupent, others (alternative drug) pediatric dose via Respirgard II nebulizer: 1–3 months: 30 mg/kg/day; 4–24 months: 45 mg/kg/day; >24 months: 30 mg/kg/day	300 mg inhaled monthly via Respirgard II nebuliser; * ≥5 year-old: same as adult dose; (not licensed in the USA but considered investigational for this condition by the FDA, licensed in Europe)
Cryptosporidiosis though <i>Cryptosporidium parvum</i> is a coccidian parasite and should be affected by anticoccidial drugs (cf. ► Coccidiocidal Drugs , Table 1), it turns out that this monoxenous coccidian parasite proves considerably refractory to any known chemotherapeutic drug; only a very few chemotherapeutic agents seem to have moderate clinical effects on life-threatening diarrhea in immunocompromised persons (AIDS patients) and in young animals	

(continued)

Treatment of Opportunistic Agents, Table 1 (continued)

DISEASE non-proprietary name (chemical group)	Adult dosage/*pediatric dosage (mg/kg b.w., or total dose/individual, oral route), miscellaneous comments
Brand name other information	
(cf. text: Drugs Acting on Cryptosporidiosis); management of cryptosporidiosis has to include fluid therapy, and nutritional support; the use of antimotility agents should be used with caution among young children	
Nitazoxanide (NZX)	400 mg NZX qd × 3 days; *1–3 years: 100 mg NZX bid × 3 days; 4–11 years: 200 mg NZX bid × 3 days; in
<i>Non-HIV infected patients:</i>	<i>HIV infected patients</i> , NZX has not consistently been shown to be superior to placebo [Amadi B et al. (2002) Lancet 360: 1375]; a small randomized, double-blind trial in symptomatic HIV patients who were not receiving highly active anti-retroviral therapy (HAART) found
NZX is approved for treatment of diarrhea caused by <i>Cryptosporidium</i> and <i>Giardia lamblia</i> , and is available in a tablet and liquid formulation: NTZ therapy reduces duration of both diarrhea and oocyst shedding; no substantial adverse reactions are reported	paromomycin (25–35 mg/kg/day p.o. in
2–4 divided doses, maximum dose: 500 mg 4 × daily) similar to placebo; azithromycin (10 mg/kg/day on d1 and 5 mg/kg/day on days 2–10) was successful in rapidly resolving enteric symptoms in 3 of 4 HIV infected children with cryptosporidiosis (<i>C. parvum</i>); oral hyperimmune bovine colostrums and oral immune globulin have variable benefits among immunocompromised patients with cryptosporidiosis; immune reconstitution resulting from HAART frequently results in clearance of <i>Cryptosporidium</i> and Microsporidia ↓ infections; therefore, effective HAART is the recommended treatment for these infections, including supportive care with hydration, correction of electrolyte abnormalities, and nutritional supplementation	
Toxoplasmosis	
The definitive host of <i>Toxoplasma gondii</i> is the cat, which passes infective oocysts in its feces; there is no satisfactory treatment, which eliminates completely oocyst shedding in cats; a combination of antimalarial drug <i>pyrimethamine</i> (PYR) and sulfadiazine is effective against tachyzoites, but not so bradyzoites; <i>clindamycin</i> affects murine toxoplasmosis, and like PYR will reduce but not eliminate oocyst output in cats; infection of humans may be postnatally acquired or congenital; the majority of acquired infections are asymptomatic and widespread among humans though prevalence varies locally (about 500 million humans have antibodies to <i>T. gondii</i> , and in most countries about 60 % of adults are seropositive); in immunosuppressed patients, including AIDS patients rupture of ‘dormant’ tissue cysts may lead to transformation of bradyzoites into tachyzoites and new multiplication; thus HIV infected patients often develop CNS (central-nervous-system) toxoplasmosis characterised by a focal encephalitis; human chemotherapy and chemoprophylaxis rely on drugs that affect tachyzoites rather than bradyzoites ‘encapsulated’ in the tissue cyst; <i>atovaquone</i> appears to be the most cytotoxic among drugs tested in the mouse model; in <i>ocular toxoplasmosis</i> with macular involvement, <i>corticosteroids</i> should also be used for an anti-inflammatory effect on the eyes; the antifolate PYR given with <i>sulfadiazine</i> is the treatment of choice for CNS toxoplasmosis; folinic acid is given concurrently to attenuate bone marrow suppression caused by PYR; length of treatment is determined by clinical response to therapy and can last for weeks; feline toxoplasmosis may be treated with clindamycin (12.5–25 mg/kg b.w. p.o. or i.m. q12h × 2 weeks) or sulfadiazine (30 mg/kg b.w.) plus PYR (0.25–0.5 mg/kg b.w.) p.o. q12h × 2 weeks or sulfadiazine (30 mg/kg b.w.) plus PYR (0.25–0.5 mg/kg b.w.) p.o. q12h × 2 weeks plus folinic acid (5 mg/day)	
Pyrimethamine (PYR) (diaminopyrimidine) plus sulfadiazine (sulfonamide)	PYR: 25–100 mg/kg/day × 3–4 weeks plus sulfadiazine 1–1.5 g qid × 3–4 weeks plus folinic acid 10 mg with each dose of PYR; *PYR: 2 mg/kg/day × 3 days, then 1 mg/kg/day (max. 25 mg/day) × 4 weeks plus sulfadiazine 100–200 mg/kg/day × 3–4 weeks plus folinic acid 10 mg with each dose of PYR; congenitally infected newborns should be treated with PYR every 2 or 3 days and sulfonamide daily for about 1 year
Daraprim, others (standard treatment, drugs of choice)	
Atovaquone (hydroxynaphthoquinone) plus pyrimethamine (alternative regimen in sulfa-intolerant patients)	Atovaquone (1.5 g p.o. bid with meals or p.c.) plus PYR and folinic acid appears to be an effective alternative in sulfa-intolerant patients
Pyrimethamine plus clindamycin	50–100 mg/day × 3–4 weeks plus clindamycin 450–600 mg per os or 600–120 mg i.v. qid plus folinic acid, 10 mg, with each dose of PYR
Alternative treatment	
Spiramycin (therapeutic use during first trimester of pregnancy)	3–4 g/day; after the first trimester, if there is no documented transmission to fetus, spiramycin can be continued until term; if it is determined that transmission has occurred in utero, therapy with PYR and sulfadiazine should be started; congenitally infected newborns should be treated with PYR every 2 or 3 days and a sulfonamide daily for about 1 year
Rovamycine, others (alternative drug)	

(continued)

Treatment of Opportunistic Agents, Table 1 (continued)

DISEASE non-proprietary name (chemical group)	Adult dosage/*pediatric dosage (mg/kg b.w., or total dose/individual, oral route), miscellaneous comments
Brand name other information	
Alternative regimens to treat CNS toxoplasmosis:	
In HIV-infected patients with cerebral toxoplasmosis, some clinicians have used PYR 50–100 mg/day after a loading dose of 200 mg with a sulfonamide and, when sulfonamide sensitivity developed, have given <i>clindamycin</i> (PYR 1.8–2.4 g/day in divided doses) instead of the sulfonamide; clindamycin with plus PYR (see above) has been proved an effective alternative for treatment of cerebral toxoplasmosis; also <i>atovaquone</i> plus PYR has been effective and well tolerated in insulfa-patients	
Chronic suppression of toxoplasmosis:	
PYR and sulfadiazine or PYR and clindamycin are the most commonly used regimens for chronic suppression of toxoplasmosis; daily PYR and sulfadiazine appears to be more effective than a twice-weekly regimen	
Pyrimethamine (PYR) plus sulfadiazine	PYR 25–50 mg per os daily plus sulfadiazine 500 mg-1 g p.o. q6h plus folinic acid, 10 mg, with each dose of PYR
Standard treatment	
Pyrimethamine (PYR) plus clindamycin	PYR 50 mg per os daily plus clindamycin 300 mg p.o. qid plus folinic acid, 10 mg, with each dose of PYR
Alternative treatment	
Primary prophylaxis of toxoplasmosis: in HIV patients: with $<100 \times 10^6/L$ CD4 cells, either trimethoprim-sulfamethoxazole, PYR plus dapsone or atovaquone with or without PYR and folinic acid can be used; primary and secondary prophylaxis may be discontinued when CD4 count increases to $>200 \times 10^6/L$ for >3 months; doses of trimethoprim-sulfamethoxazole used to prevent <i>Pneumocystis</i> pneumonia (PCP, see above) may also prevent first episodes of toxoplasmosis; daily dapsone and weekly pyrimethamine or both twice weekly may also prevent first episodes of toxoplasmosis	
Microsporidiosis current information indicates that immunocompromised patients (as in HIV infected individuals) are at the greatest risk of developing microsporidial disease patterns such as ocular infections involving conjunctival, corneal epithelium and even corneal stroma (keratoconjunctivitis) or enteritic infections associated with enteritis, colangitis and diarrhoea; there may also be multiorgan infection or systemic dissemination of microsporidians, including the liver, lungs and kidneys; treatment of microsporidial infections is problematic because of the intracellular habitat of the parasite stages and the resistant nature of the spores (for more information see ► Microsporidiosis)	
Ocular infections due to <i>Encephalitozoon hellem</i> , <i>Encephalitozoon cuniculi</i> , <i>Vittaforma corneae</i> (<i>Nosema corneum</i>)	
Albendazole (benzimidazole carbamate) licensed for treatment of various helminthes animals (cf. <i>Nematocidal Drugs</i> , Animals Benzimidazole Compounds) and humans (cf. ► Nematocidal Drugs , <i>Man</i> , Table 1)	400 mg bid (not licensed in the USA but considered investigational for this condition by the FDA, licensed in Europe and elsewhere); ocular lesions due to <i>E. hellem</i> in HIV infected patients have also responded to <i>fumagillin</i> eyedrops prepared from Fumidil-B, a commercial product, used to control a microsporidial disease of honey bees; for lesions due to <i>V. corneae</i> , topical therapy is generally not effective and keratoplasty may be required
Albenza, others (drug of choice)	
Intestinal infections due to <i>Encephalitozoon bienersi</i> , and <i>Encephalitozoon (Septata) intestinalis</i>	
Albendazole (drug of choice)	400 mg bid octreotide (a somatostatin analogue, Sanostatin) has provided symptomatic relief in some patients with large volume diarrhoea; oral fumagillin has been effective in treating <i>E. bienersi</i> but has been associated with thrombocytopenia
Disseminated infections due to <i>Encephalitozoon hellem</i> , <i>Encephalitozoon cuniculi</i> , <i>Encephalitozoon intestinalis</i> , and <i>Pleistophora</i> sp.	
Albendazole (drug of choice)	400 mg bid; there is no established treatment for <i>Pleistophora</i>

Dosages listed in the table refer to information from manufacturer or literature, preferably from The Medical Letter (1998 and 2004) 'Drugs for parasitic Infections'

Data given in this table have no claim to full information

Abbreviations: The letter *d* stands for day (days), *qd* daily (quaque die), *qh* each hour, *bid* twice daily, *tid* three times per day, *qid* four times per day (quarter in die), *p.c.* (*post cibum*) after meals

or other opportunistic infections like candidiasis. Alternative treatment (for regimens cf. Table 1) may be used for patients with mild to moderate or even severe PCP who have failed or have shown intolerance to the standard treatment (trimethoprim + sulfamethoxazole). For cases of moderate to severe PCP, alternative drugs may be pentamidine (IV) or atovaquone (PO) or dapsone (sulfone with antileprosy activity) given concurrently with trimethoprim. All these drugs appear to be less active but better tolerated than trimethoprim plus sulfamethoxazole. This seems to be true also for the antimalarial atovaquone. Simultaneous use of clindamycin (IV or PO) with oral primaquine (► [Malariacidal Drugs](#)) has been successful in patients with mild to moderate PCP. For primary and secondary ► [chemoprophylaxis](#) of PCP, standard treatment is oral trimethoprim plus sulfamethoxazole (cf. Table 1). For alternative treatment, dapsone may be used alone, or concurrently with pyrimethamine plus folinic acid. Aerosolised pentamidine (e.g., NebuPent, 300 mg inhaled monthly via a Respigard II nebuliser) is well tolerated but less effective than trimethoprim plus sulfamethoxazole and, in patients with <100 CD4 cells, less active than dapsone. Chemoprophylaxis against PCP is also needed in patients with AIDS-related complex diseases or those with bone marrow or solid organ transplants. In absence of prophylaxis most of heart-lung, and lung allograft recipients will probably develop PCP. Supporting treatment as elevation of arterial oxygen pressure, support of lung function, or corticosteroid therapy along with specific causal agents against PCP will reduce the frequency of mortality in immunocompromised patients, particularly in those suffering from AIDS.

Drugs Acting on Cryptosporidiosis

Species of the genus *Cryptosporidium* are coccidian parasites that infect epithelial cells (extracytoplasmic) of the intestinal and respiratory tract of vertebrates (see also ► [Cryptosporidium](#) for life cycle and ► [Coccidiocidal Drugs](#)). Although immunocompetent hosts show no or

only mild clinical signs after *C. parvum* infections immunosuppressed hosts may suffer from life-threatening watery ► [diarrhoea](#) caused by enteritis of the small intestine. Infections are due to infective oocysts (=sporocysts) passed in feces of carriers in the environment. Transmission may occur by food/feed or water supplies containing sporulated oocysts, or by droplet infections. Outbreaks of the disease are mainly seen in **young animals** or **neonates** (calves, lambs, piglets, foals and zoo, pet or laboratory animals). The disease in livestock is associated with intensive husbandry, seasonal breeding, and mixed grazing practices (feed, water and holding facilities contaminated with ► [oocyst](#)). Clinical signs are weakness, dullness, rough coat, weight loss and mortality. In **humans** the severity of infection depends on immunocompetence of the patient. Immunosuppressed humans suffering from AIDS can show intractable diarrhea causing ► [dehydration](#), weakness, considerable weight loss and even mortality.

No consistently effective therapy or chemoprophylaxis is available for either cryptosporidiosis or **microsporidiosis** (cf. Table 1). Only a few drugs show some activity against *C. parvum* infections and are approved for the use in animals and humans for this indication (e.g., halofuginone lactate cf. ► [Theileriacidal Drugs](#)). Many approaches to anticryptosporidial efficacy of commercial drugs have failed in improving symptoms in ruminants suffering from *C. parvum* infections. Several anticoccidials, like sulfonamides, lasalocid sodium, halofuginone lactate, decoquinate or paromomycin (available as additives in-feed, cf. ► [Coccidiocidal Drugs](#), or other dosage forms for oral or parenteral administration) have been found to be insufficiently effective in controlling or even eradicating *C. parvum* infection in calves and kids. They may exhibit positive clinical short-term effects such as improvement of watery diarrhea and reduction of oocyst output in feces. Monoclonal antibodies raised against *C. parvum* may reduce clinical signs in *C. parvum* infected laboratory animals. Therefore, drug treatment should be associated with **strict measures of** ► [hygiene](#) (which should also include the farm personnel) and sanitation, such as disinfection (ammonium hydroxide) and

thorough cleaning in contaminated farms. During the calving period, calving cows must be separated from other animals and newborn calves too. Oral and parenteral rehydration therapy is essential in animals with severe diarrhea to maintain the fluid balance. Also management in AIDS patients has principally included fluid therapy, use of antidiarrheal agents and nutritional support. For treatment of microsporidiosis, **albendazole** decreases diarrhea (sometimes eradication of the organism) caused by *Encephalitozoon intestinales*. **Nitazoxanide** has been used for treatment of *E. bienewsi* infection among HIV-infected adults (for Fumagillin treatment cf. Table 1).

Drugs Acting on Toxoplasmosis

The cyst-forming coccidian parasite ► *Toxoplasma gondii* is widespread in human beings and many warm-blooded animals, and cats including wild Felidae, are the only definitive hosts excreting *T. gondii* oocysts in their feces. The domestic cat appears to be the major source of contamination with oocyst since a cat can excrete millions of oocyst surviving for long periods under ordinary ► **environmental conditions** (e.g., in moist soil). Despite the fact that cats are frequently infected clinical signs are rare. Feline toxoplasmosis can be treated with clindamycin or sulfadiazine plus antifolates (cf. Table 1).

Ovine toxoplasmosis may be associated with ► **abortion** in ewes and perinatal mortality in lambs. Toxovax (Internet), commercially available in Europe and New Zealand, is a live vaccine containing *T. gondii* ► **tachyzoites** of the S 48 “incomplete” strain. The vaccine is used for the control of ovine toxoplasmosis and reduces fetal losses in sheep in endemic areas (withdrawal time: 6 weeks).

Human toxoplasmosis is most often the result of ingestion of tissue cysts in raw or undercooked meat from pigs, sheep and rabbits (less prevalent in cattle). Exposure to heat (70 °C) and cold (−15 °C) can kill parasites in meat. Good hygiene and sanitation can help to control infection; hands of people preparing raw meat and all materials

(cutting boards, knives, etc.) coming in contact with uncooked meat should be washed with soap and water, and rinsed thereafter thoroughly with tap water. To avoid oral infection with oocysts shed by cats gloves should be worn while gardening, and vegetables should be washed thoroughly before eating because of possible contamination with cat feces. Pet cats should be fed only cooked food. **Pregnant women**, in particular, should not eat raw or uncooked meat and avoid contact with cats and soil because of risk of a congenital infection. The infected fetus may develop full tetrad of signs, i.e., retinochoroiditis, hydrocephalus, convulsions and intracerebral calcification. In the USA the overall risk for maternal-fetal transmission in women without HIV infection who acquire *primary Toxoplasma* infection during pregnancy is 29 %; the risk of primary congenital infection sharply increases during the last few weeks of pregnancy (up to 81 %). Infection of the fetus in early gestation usually results in more severe involvement.

Patients with AIDS often develop central nervous system (CNS) toxoplasmosis (focal encephalitis). **Currently used drugs** and dosages for treating the disease in individuals are shown in Table 1. In AIDS patients, ‘dormant’ developmental stages of *T. gondii* (tissue cysts containing ► **bradyzoites**) are reactivated thereby altering the latent infection to an acute one. The drug of choice for treating CNS toxoplasmic ► **encephalitis** is oral pyrimethamine (e.g., Daraprim GSK) plus sulfadiazine, usually given for 3–5 weeks depending on clinical response, plus folinic acid (for dosage regimen cf. Table 1). Concurrently given drugs may cause severe adverse reactions in approx. Forty percent of the so treated patients, though folinic acid may reduce bone marrow suppression caused by pyrimethamine. *Alternative regimens* can be used in patients with failure to pyrimethamine plus sulfadiazine treatment or intolerance to these drugs. On the other hand these regimens may be used for treatment of mild to moderate cerebral toxoplasmosis as oral pyrimethamine given concurrently with clindamycin or other atovaquone (ATQ) plus pyrimethamine (PYR) and folinic acid, or ATQ with sulfadiazine (SFD) alone, or ATQ as a single agent in patients intolerant to both PYR and

SFD, or trimethoprim plus sulfamethoxazole alone: all these alternative regimens have been used in adults only and have not been studied among children. Experimental drugs with good activity against *T. gondii* in mice are diclazuril and toltrazuril (► [Coccidiocidal Drugs](#)). Although the action of diclazuril on tachyzoites can be enhanced by combination with pyrimethamine this drug mixture is not able to prevent ► [tissue cyst](#) formation in surviving mice.

Trematocidal Drugs

Synonyms

Trematodocidal Drugs

Trematodes

Name

Greek: *trema* = hollow (means the sucker), *todein* = porting.

The term Trematodes comprising digeneans and monogeneans is thought by some authors to be an artificial grouping since all morphological evidence, especially at the ultrastructural level, suggests that the ► [Monogenea](#) are more closely related to the Cestoda than to the ► [Digenea](#) and ► [Aspidogastrea](#) (► [Platyhelminthes/System](#)).

Trematodocidal Drugs

²Bayer HealthCare AG, Division Animal Health, Leverkusen, Germany

Current Status of Structurally Different Flukicides

Some of the medications are no longer available, but will be considered for historical understanding

of drug evolution and use. The anthelmintic activity of carbon tetrachloride and hexachloroethane was discovered between 1921 and 1926. Despite their high toxicity and variable efficacy, these halogenated hydrocarbons had been used for many years in the chemotherapy of various trematode diseases, primarily against *Fasciola* infections in cattle. Later, hexachloroparaxylene (*Hetol* former Hoechst), and the carbon acid piperazine derivative 1-β,β,β-tris-(p-chloro-phenyl)-propionyl-4-methyl-piperazine hydrochloride (*Hetolin*, former Hoechst) showed better tolerability and enhanced efficacy against adult liver flukes such as *F. hepatica* and *Dicrocoelium dendriticum*, and paramphistomes (rumen flukes) in cattle and sheep. Current flukicides for use in cattle and sheep come from various chemical groups: **Halogenated phenols and bisphenols**, e.g., hexachlorophene (used since the late 1950s but now discontinued in most countries), *bithionol* (with a sulfur bridge between the two phenol rings), which is used to a limited extent against *F. hepatica* and intestinal fluke infections of humans (cf. Table 2), and the corresponding structural variants *bithionol sulfoxide* and *bithionolate sodium*. They were predominantly used as antimicrobials with activity against bacteria and fungi. *Niclofolan* (syn. menichlophan, having two phenol rings linked directly via a carbon bond) is highly active against mature *F. hepatica* but has been discontinued in many countries. In the late 1960s, the monophenolic *nitroxylin* (syn. nitroxinil, having an electron-withdrawing nitro group and a cyano group in ortho- and para-position) was developed in the UK as an injectable formulation. In Australia, the drug is currently approved for the control and treatment of liver fluke, barber's pole worm (*Haemonchus contortus*) and nodule worm (*Oesophagostomum*) infections in cattle and sheep (cf. Table 1). *Bromofenofos* (or bromophenophos, an organophosphate structurally similar to a masked bisphenol derivative, former Acedist Merial) and the monophenolic resorcylanilide *resorantel* (former Terenol Hoechst) are no longer available in EC, USA, Australia, and elsewhere. In cattle and sheep, the two drugs proved highly effective against mature

Trematodocidal Drugs, Table 1 Drugs used against trematode infections of domestic animals

Chemical group international nonproprietary name (INN) (single oral dose, mg/kg body weight = b. w.), other information	*Drug product dose form (formulation), withdrawal time (WT) days (d) before slaughter, manufacturer, supplier, other information	Characteristics: miscellaneous comments on pharmacokinetics, metabolism, mode of action, toxicity, and limitations
Monophenolic derivatives		
Nitroxylin (NXN) (syn. <i>nitroxinil</i> : EC) (8.5–10.2 s.c. sheep, cattle) (cattle: *1.5 mL/50 kg b.w., sheep: *0.25 mL/10 kg b.w.) limitation: contraindicated for use in lactating animals	*Trodax (Fort Dodge, Merial, Australia), (340 g NXN/L as eglumine salt), liquid for subcutaneous injection (usually as water-soluble N-ethylglucamine salt), WT: sheep, cattle 28 days (not approved in the USA, evaluated by EMEA, EC: no drug products available in Germany, elsewhere)	Developed in the UK as an injectable fasciolicide in the late 1960s; it is effective against <i>Fasciola hepatica</i> and <i>F. gigantica</i> infections but not the rumen fluke (<i>Paramphistomum</i>) in cattle and sheep; it has some activity against GI nematodes such as <i>Haemonchus contortus</i> and <i>Parafilaria bovicola</i> ; there is a reasonably good activity against <i>F. hepatica</i> (activity: 50–90 %:
Flukes aged 6–8 weeks is erratic, 90–99 %: flukes aged 10–14 weeks); it exhibits good activity against <i>F. gigantica</i> but not so against paramphistomes; approved indications in Australia: sheep and cattle: liver fluke; sheep: plus barber's pole worm; cattle: plus barber's pole worm, hookworms, and nodule worm); NXN is also administered to game birds (pheasant, red legged partridge poult) in drinking water for the treatment syngamiasis caused by <i>Syngamus trachea</i> and/or <i>Cyathostoma bronchialis</i> (evaluated by EMEA, EC); at recommended dose, its antitrematodal effect against immature flukes is slightly inferior to that of rafoxanide (↓); mode of action: it is of similar structure to the herbicides ioxynil and bromoxynil; like them it is an uncoupler of oxidative phosphorylation (27–35 μM = 93–121 μg/mL in rat liver mitochondria); its mode of action is attributed to this effect; it also affects adversely fluke spermatogenesis (reduced fertile eggs of surviving flukes); pharmacokinetics and metabolism: peak plasma concentration (in rats) ~67 μg/mL 5 h after dosing with 10 mg/kg b.w.; terminal half-life in plasma was ~22 h; excretion was predominantly via the urine and consisted of a mixture of metabolites together with some unchanged NXN; in cattle, sheep and rabbits, the drug was highly bound (97–98 %) to plasma protein, and in all species residues in plasma were higher than those in tissues and consisted almost entirely of NXN; in cattle and sheep it is extensively metabolized, and unmetabolized NXN was the major component of the residues in muscle and fat; chemical structure of some of the metabolites (e.g., 4-cyano-2-nitrophenol) suggested that they would have toxicological properties similar to those of NXN; tolerability: it is well tolerated in cattle and sheep at the recommended dose level; doses of 20 mg/kg b.w. may cause minimal side effects such as hyperthermia and hyperpnoea associated with uncoupling of oxidative phosphorylation; doses of 40 mg/kg b.w. and above may cause death of target species; administration of *Trodax may cause some yellow staining of fleece in sheep, and local reactions at injection site		
Salicylanilides		
Bromsalans (various mixtures of <i>tribromsalan</i> and <i>dibromsalan</i>) (30–50 sheep)	Drug products may be available in some countries; (no longer approved in the USA and Australia?, not approved in EC, elsewhere)	For treatment of mature and immature liver fluke (<i>Fasciola hepatica</i>) infections; drug mixtures show good but somewhat erratic activity (40–98 %) against mature <i>F. hepatica</i>
Aged 12 weeks and above; efficacy against juvenile flukes (6–10-week-old) is good (90–99 %); maximum tolerated dose in sheep is approx. 90 mg/kg b.w. (safety index ~3); in cattle, bromsalans are not compatible with benzimidazole carbamates (BZs) (cf. Nematocidal Drugs, Animals/Table 1 → BZs, such as fenbendazole, oxfendazole albendazole); contraindication: do not administer BZs in cattle within 7 days of a <i>bromsalans</i> flukicide: simultaneous use of BZs with <i>bromsalans</i> causes severe (fatal) adverse effects in cattle		
Oxyclozanide/levamisole HCl (OCZ/LEV) (150 g OCZ//64 g LEV/L) (5 mL/45 kg b.w. cattle) (1 mL/10 kg b.w. sheep)	*Coopers Nilzan LV (Schering Plough Australia), oral liquid (drench), WT: cattle 14 days, milk 0 day, sheep 14 days (see limitations: milk)	OCZ was introduced for its fasciolicidal activity in 1966; it is active against adult liver fluke infections and in some countries combined with LEV hydrochloride (HCl) to offer broad-spectrum anthelmintic treatment; OCZ

(continued)

Trematodocidal Drugs, Table 1 (continued)

Chemical group international nonproprietary name (INN) (single oral dose, mg/kg body weight = b. w.), other information	*Drug product dose form (formulation), withdrawal time (WT) days (d) before slaughter, manufacturer, supplier, other information	Characteristics: miscellaneous comments on pharmacokinetics, metabolism, mode of action, toxicity, and limitations
Is highly active against mature <i>Fasciola hepatica</i> (efficacy 90–99 % against flukes aged 10–14 weeks); repeated doses (3 × 15 mg/kg) show some activity against immature flukes; drug has been primarily used in treating acute fascioliasis; it has a moderate effect against the rumen fluke (<i>Paramphistomum</i> : immature stages: cattle ~60 %, sheep 80–92 %, and mature		
Stages: cattle, sheep 70–90 %); OCZ (at 15 mg/kg) has been found partially effective against immature and mature <i>Fascioloides magna</i> in cattle; however, this effect is considered unsatisfactory since a single migrating fluke can kill the host; it exhibits efficacy against the fluke <i>Notocotylus attenuatus</i> in ducks (at 15 mg/kg b.w., well-tolerated oral liquid, or 30 mg/kg in feed,); maximum tolerated dose of OCZ in sheep is 60 mg/kg b.w. (safety index ~4); mode of action : like other salicylanilides and substituted phenols it is an uncoupler of oxidative phosphorylation; following absorption in the gut it is excreted as an active glucuronide metabolite into bile (terminal half-life 6.5 days); it has been used at therapeutic doses in debilitated and pregnant animals without side effects; OCZ/LEV include efficacy against roundworms, including lungworms, and BZs resistant <i>Haemonchus contortus</i> particularly in sheep (details cf. Nematocidal Drugs, Animals/Table 1 levamisole); it should also assist in removal of tapeworm segments in sheep and lambs; limitations : do not use *Nilzan LV in sheep, which are producing or may in future produce milk or milk products for human consumption; do not administer to dogs or horses		
Rafoxanide (RFX) (7.5–15 mg/kg b.w. per os cattle, sheep) like <i>oxyclozanide</i> , RFX is a salicylanilide; [current status in EC (EMA): establishment of MRLs was requested for nonlactating cattle and sheep: RFX is included in Annex I Council Regulation (EEC) No. 2377/90, currently no drug products on the German market, not approved in USA, Australia, and elsewhere] RFX was developed in 1969 and subsequently has had commercial use for fascioliasis in various countries (Australia, SA, UK, Europe, Brazil); it proved highly active against mature <i>Fasciola hepatica</i> , and <i>F. gigantica</i> (efficacy ~100 % against flukes aged 12–14 weeks, 85–97 % against flukes aged 6–8 weeks, and 50–85 % against flukes aged 4 weeks); the drug has been used for strategic treatment and chemoprophylaxis (long-lasting effect due to binding of RFX to plasma proteins) to reduce pasture contamination; at 10 and 15 mg/kg b.w., it proves 100 % effective against immature and mature <i>Fascioloides magna</i> and juvenile paramphistomes in sheep; it is also active against GI nematodes (<i>Haemonchus</i> , <i>Bunostomum</i> , <i>Gaigeria</i> , and <i>Oesophagostomum</i>) and the sheep nasal bot fly (<i>Oestrus ovis</i>); at recommended dose, the drug is well tolerated in sheep and cattle of all ages; mode of action is uncoupling of oxidative phosphorylation of flukes, including reduced ATP levels, decreased glycogen content, and accumulation of succinate; in sheep, drug is extensively bound (>99 %) to plasma proteins and has a long terminal half-life (~17 days), maximum tolerated dose (sheep) is ~45 mg/kg b.w. per os; RFX is contraindicated in lactating animals and may have an extreme long withdrawal times (several months) in cattle and sheep		
Closantel (CST) (7.5 sheep, 10 cattle) approved indications : for the sustained control of <i>H. contortus</i> and control of liver fluke (and nasal bots in sheep and lambs) limitations : do not use in animals which are producing or may in future produce milk or milk products for human consumption	*Closamax Closantel (Pharmtech Australia, elsewhere), others, oral liquid for sheep and lambs (37.5 g CST/1 L: 1 mL/5 kg b.w. = 7.5 mg/kg bw), WT: sheep, lambs 28 days; *Flukiver (Janssen-Cilag Germany, elsewhere), oral liquid (54.375 mg CST Na/ 1 mL: 1 mL/5 kg b.w. = 10.87 mg/kg b.w.) WT: cattle 28 days, sheep 42 days	Introduced principally as a flukicide for sheep and cattle in the 1970s; its efficacy in either host is >95 % for 8-week-old and adult <i>Fasciola hepatica</i> (efficacy 70–80 % against 6-week-old stages migrating in the liver); at 15 mg/kg b.w. CST is active (~95–98 %) against 8-week-old <i>Fascioloides magna</i> in sheep; it is inactive against the rumen flukes (paramphistomes); at
Recommended dose, it shows also activity against strains of Barber's pole worm (<i>Haemonchus contortus</i>) of sheep resistant to ivermectin, BZs, levamisole, morantel, and rafoxanide; however, there are strains of <i>H. contortus</i> , which have developed resistance to CST; it has been used in horses to prevent or reduce <i>Strongylus vulgaris</i> infections and infestations with bots (<i>Gasterophilus</i> spp.) and nasal bot <i>Oestrus ovis</i> in sheep; it is also active against adult stages of <i>Ancylostoma caninum</i> ; mode of action : flukicide action of CST has been linked to its capacity for uncoupling electron-transport-associated phosphorylation and possibly the site-1 phosphorylation of ADP associated with reduction of fumarate to succinate; pharmacokinetic and metabolism : like rafoxanide, CST is extensively bound (>99 %) to plasma proteins (mainly albumin) and has a long terminal half-life (~15 days); metabolic studies in cattle have shown that CST was poorly metabolized in the majority of tissues, except liver; it represented at least 70 % of total residues in fat, 80 % in kidneys, and 100 % in muscle: on the other hand it represented only 10 % in liver; kinetic studies using radiolabeled elements have shown that the radioactivity concentration ratio between plasma and tissues did not vary with time for the		

(continued)

Trematodocidal Drugs, Table 1 (continued)

Chemical group international nonproprietary name (INN) (single oral dose, mg/kg body weight = b. w.), other information	*Drug product dose form (formulation), withdrawal time (WT) days (d) before slaughter, manufacturer, supplier, other information	Characteristics: miscellaneous comments on pharmacokinetics, metabolism, mode of action, toxicity, and limitations
bovine nor for the ovine species; prolonged residuals may prevent <i>Haemonchus</i> and <i>Fasciola</i> infections up to 60 days post treatment; CST is primarily excreted via feces (80 %; urine <05 %); tolerability : the drug is well tolerated in sheep and cattle (also in reproduction studies in rams, ewes, and bulls); safety margin in sheep and cattle is ~4; overdosing (>4 times the therapeutic dose) may cause ataxia, weakness, inappetence, and visual disorders (and blindness); there is no antidote		
*1 closantel (CST)/ oxfendazole (OFZ) (7.5/4.52 sheep) *2 closantel (CST)/ abamectin (ABA) (10/0.2 sheep) *2 limitations : do not use in lambs under 6 (six) weeks of age; do not use in lambs under 10 kg b.w. (closantel/albendazole cf. albendazole ↓)	1*Cloisicomb (Virbac BASF Australia, elsewhere) others, oral liquid (drench) with sustained action (37.5 g CST/L//22.6 g OFZ/L: 1 mL/5 kg b.w.), WT: sheep 28 days 2*Genesis XTRA (Ancare Australia, elsewhere), oral liquid (drench) with sustained action (50 g CST/L// 1gABA/L: 1 mL/5 kg b.w.), WT: sheep 49 days	1* for control of susceptible mature and immature GI nematodes and tapeworms (<i>Moniezia</i> spp.), lungworms (<i>Dictyocaulus filaria</i>), liver fluke (<i>Fasciola hepatica</i>) including 4-week-old immature stages, all stages of nasal bots (<i>Oestrus ovis</i>), and sustained control of susceptible Barber's pole worm (<i>Haemonchus contortus</i>) in sheep; can be used at recommended
Dose in sheep of all ages including pregnant ewes; 2* for control and treatment of roundworms, nasal bot, itch mite (<i>Psorergates ovis</i>), and mature and late immature liver fluke in sheep with sustained activity against resistant strains of Barber's pole worm in sheep (including strains resistant to macrocyclic lactones); limitations : do not use in ewes, which are producing or may in the future produce milk or milk products for human consumption		
Bisanilino Compounds or Phenoxyalkanes : diamfenitide (former *Coriban Wellcome) syn. acemidophene, former USSR (100 mg/kg per os sheep, goats) no longer approved in the USA, Australia, Germany (EC), and elsewhere; chemically a bisacetamide or bisacetanilide (or may be regarded as masked aromatic diamidine) that is enzymatically converted in liver cells of sheep (deacetylation by deacylases) to the bisanilino compound; this amine metabolite is highly effective (91–100 %) against early immature <i>Fasciola hepatica</i> aged 1 day to 9 weeks; thus very juvenile flukes passing through the liver parenchyma become rapidly killed by high local concentrations of the bisanilino compound; older and mature flukes located in bile ducts may survive because of obviously quick catabolism of the very toxic bisanilino compound, and concentrations of the active metabolite till reaching mature flukes are too low to kill them; thus there is a gradually lower activity (70–50 %) with aging of the fluke; the drug was very useful for treating acute fascioliasis and in prophylactic control programs against liver fluke disease in sheep (e.g., repeated treatment, interval 6–8-weeks: 2× in spring and 2× in autumn, or combined with a flukicide acting against flukes aged 6–14 weeks); at 200 mg/kg it proved active (85–93 %) against adult stages of the small liver fluke (<i>Dicrocoelium dendriticum</i>) in sheep; following oral administration, the drug was absorbed into blood and distributed via circulation throughout the body (peak concentration in liver and gallbladder was reached 3 days post dosing, and then drug levels declined to negligible values within 7 days); diamfenitide was well tolerated at recommended dose (no teratogenic in pregnant ewes, or adverse effects on fertility in ewes or rams, maximum tolerated dose in sheep: 400 mg/kg b.w.; 1,600 mg/kg b.w. caused low incidence of mortality)		
Benzimidazoles (BZs) among the BZs (cf. Nematocidal Drugs, Animals), only albendazole (ABZ ↓) and triclabendazole (TCBZ ↓) have therapeutic activity against adult stages of <i>Fasciola hepatica</i> and <i>F. magna</i> in cattle and sheep; fenbendazole (FBZ) is not as effective as ABZ and TCBZ against the liver fluke (not approved indication, and others following) but apparently has good activity against <i>Dicrocoelium dendriticum</i> in sheep at 150 mg/kg × 1, or 20 mg/kg/day × 5 days, and some activity (~70 % after 7.5 mg/kg bw in feed for 6 days) against adult and migrating (immature) stages of rumen flukes (<i>Paramphistomum</i>) of cattle, and against <i>F. gigantica</i> infection (~90 %: 5 mg/kg b.w. × 1) in sheep; in experimental studies, FBZ has been shown to cure infections with the blood fluke <i>Heterobilharzia americana</i> (40 mg/kg b.w. daily for 10 day) in dogs, and infections with pancreatic fluke <i>Eurytrema procyonis</i> (30 mg/kg b.w. daily for 6 days) in cats; at enhanced dose levels (15 mg/kg b.w.), oxfendazole shows also good activity (~95 %) against adult stages of <i>F. hepatica</i> in sheep and cattle; also other BZs proved to be active (~90 %) against adult <i>D. dendriticum</i> , e.g., albendazole (7.5–15 mg/kg × 2: weekly interval), cambendazole (25 mg/kg × 1), thiabendazole (200 mg/kg × 1), or mebendazole (20 mg/kg × 1); proved uneconomically and were illegal at enhanced doses (15–20 mg/kg b.w.), netobimin (prodrug of ABZ/ABZ sulfoxide) affects adult stages of flukes such as <i>D. dendriticum</i> (90–98 % efficacy) and <i>F. hepatica</i> (~90 % efficacy); however, most of these doses proved uneconomically;		

(continued)

Trematodocidal Drugs, Table 1 (continued)

Chemical group international nonproprietary name (INN) (single oral dose, mg/kg body weight = b. w.), other information	*Drug product dose form (formulation), withdrawal time (WT) days (d) before slaughter, manufacturer, supplier, other information	Characteristics: miscellaneous comments on pharmacokinetics, metabolism, mode of action, toxicity, and limitations
contraindication: do not administer BZs within 7 days of a bromsalans flukicide because of severe adverse reactions which result after coadministration of these drugs and which may be fatal in cattle		
Triclabendazole (TCBZ) (12 cattle) (10 sheep, goats) 2*Fasinex 120 (Novartis AH Australia) others, oral liquid for cattle and sheep (120 g TCBZ/L: cattle 5 mL/50 kg b.w., sheep 1 mL/12 kg b.w.), WT: sheep, cattle 28 days, 3*Fasinex 10 % (Novartis AH Germany, elsewhere), oral liquid for cattle and sheep (10 g TCBZ/100 mL: cattle 6 mL/50 kg b. w., sheep 1 mL/10 kg b.w.), WT: sheep, cattle 50 day	1*Fasinex 100 (Novartis AH Australia), oral paste (100 g TCBZ/L: cattle 6 mL/50 kg b.w., sheep 1 mL/10 kg bw), WT: sheep, cattle 21 day, 1*, 2*, 3* indications: for treatment of susceptible early immature, immature and mature liver fluke in sheep, cattle, and goats of all ages, including pregnant animals 1*, 2*, 3* limitations: do not use in lactating animals where milk or milk products may be used for human consumption	A thiobenzimidazole derivative introduced in 1983 as a flukicide for use in cattle and sheep in Europe, Australia, SA, USA (no longer approved), and elsewhere; it has been investigated as a fasciolicide in <i>humans</i> showing promising results in treating human fascioliasis, it appears to be a safe and effective drug; it is now used as drug of choice for the treatment of <i>F. hepatica</i> infections in humans (cf. Table 2); in <i>veterinary medicine</i> , use of TCBZ is limited to <i>liver fluke</i> infection in cattle, sheep, and goats and some other fluke
Infections of horses and wild animals (e.g., deer); it is principally active against adult flukes, and immature stages of <i>F. hepatica</i> in sheep are affected (98–100 % efficacy) by gradually elevating the dosage of the drug (2.5 mg/kg b.w. 12-week-old flukes, 5 mg/kg b.w. 10-week-old flukes, 10 mg/kg 6–8-week-old flukes, 12.5 mg/kg 1–4-week-old flukes, and 15 mg/kg 1-day-old flukes); thus doses of 10 mg/kg for sheep and 12 mg/kg for cattle are recommended in either acute, subacute, or chronic fascioliasis; typically, an oral dose of 10 or 12 mg/kg b.w. is administered to sheep and cattle, respectively, at 8–10-week intervals during the fluke season, or at 5–6 week intervals in acute or subacute cases; TCBZ proved effective against <i>F. hepatica</i> infections in horses (12 mg/kg), <i>F. gigantica</i> in cattle (12 mg/kg), and <i>Fascioloides magna</i> in deer (10 mg/kg) and sheep (20 mg/kg); pharmacokinetics and metabolism: following oral or intraruminal administration TCBZ is rapidly metabolized to its sulfoxide and sulfone (maximum plasma concentrations 12–38 h after dosing); metabolites are bound to albumin and persist in plasma for up to 7 days; excretion is chiefly via bile (~50 %) and then feces; EMEA/CVMP/320386/2005-FINAL → TCBZ: in a radiometric study in cattle, urine and feces elimination accounted for 2.2 % and 76 % of the 12 mg/kg b.w. dose, respectively, equaling a total 7 days elimination of 81.49 % of the administered dose; absorption (urine content and unrecovered dose) accounted for 21 % of the administered dose; pharmacokinetic studies in rats, rabbits, dogs, sheep, cattle, goats, and humans indicated qualitative similarities in metabolism with sulfone, sulfoxide, ketone, and the 4-hydroxyderivatives of TCBZ identified in plasma and feces; the only metabolite identified in urine was 2-benzimidazolone; in the rat the predominant identifiable metabolites in feces were the sulfoxide and 4-hydroxy-derivatives; in sheep and goats, TCBZ and 4-hydroxyderivatives were the major components; plasma kinetics studies of sulfoxide and sulfone derivatives in various species after oral dosing showed the sulfoxide to predominate in rabbits, sheep, and humans, and the sulfone in the horse, dog, and cattle; pharmacokinetics in most species appear to be linear, although there is evidence of a deviation from linearity in the rabbit, possibly due to coprophagy; plasma T _{max} for the sulfoxide was around 6–12 h in most species, 22 h in cattle, at oral doses of 10–12 mg TCBZ/kg b.w.; plasma T _{max} for sulfone was around 12–30 h in most species and 72 h in cattle; tolerability: TCBZ is a safe and well-tolerated drug at recommended dose (safety index > 10), and can be simultaneously used with other nematocidal drugs (cf. fixed-dose combinations ↓: TCBZ has no effect on nematodes, including <i>Haemonchus contortus</i>); maximum tolerated dose in sheep is 200 mg/kg (has not yet been reported in cattle, or goat); on the Australian market there are a variety of drug products from various suppliers that contain TCBZ and a nematocidal drug (examples see below)		
*1 triclabendazole (TCBZ)/ oxfendazole (OFZ) (12/4.53 cattle)	1*Flukazole Combination (Virbac BASF Australia); oral liquid for cattle (120 g TCBZ/L/45.3 g OFZ/L: 1 mL/10 kg bw), WT: cattle 21 day	1*: for control of BZ-sensitive mature and immature roundworms, lungworms, tapeworms, and early immature, immature, and mature liver fluke in cattle; limitations: do not use in cows which are producing milk or milk products for human consumption; do not administer

(continued)

Trematodocidal Drugs, Table 1 (continued)

Chemical group international nonproprietary name (INN) (single oral dose, mg/kg body weight = b. w.), other information	*Drug product dose form (formulation), withdrawal time (WT) days (d) before slaughter, manufacturer, supplier, other information	Characteristics: miscellaneous comments on pharmacokinetics, metabolism, mode of action, toxicity, and limitations
		within 7 days of a bromsalans flukicide
Triclabendazole (TCBZ)/ ivermectin (IVER) *2 (12/0.2 cattle) *3 (24/1.5 topically cattle) (240 g TCBZ/L// 15 g IVER/L: 1 mL/10 kg bw)	2*Fasimec Cattle Oral (Novartis AH Australia) others, oral liquid for cattle (120 g TCBZ/L//2 g IVER/ L: 5 mL/50 kg b.w.), WT: 21 day 3* Coopers Sovereign Pour-ON (Schering-Plough Australia) topical liquid for cattle; WT: cattle 28 days	2*: for treatment of TCBZ-sensitive early immature, immature, and mature liver fluke in cattle; for treatment and control of IVER sensitive strains of roundworms and lungworm, and sucking lice of cattle; not to be used for animals producing milk for human consumption or processing 3*: for treatment and control of IVER-sensitive GI roundworms, lungworm, and adult liver fluke of cattle; do not use on dairy cows except replacement heifers; do not use on dairy replacement heifers within 70 day (10 weeks) of calving
*4 triclabendazole (TCBZ)/ abamectin (ABA) (30/0.5 topically cattle)	4*Fasimec Cattle Pour-On (Novartis AH Australia) others, topical liquid for cattle (300 mg TCBZ/mL//5 mg ABA/mL: 1 mL/10 kg bw), WT: cattle 49 days	4*: for treatment and control of roundworms, liver fluke (all three stages), and external parasites of beef cattle; do not use in dairy animals producing or which will in the future be producing milk for human consumption; this product is contraindicated for use in calves under 50 kg b.w.
*5 triclabendazole (TCBZ)/ moxidectin (MOX) (10/0.2 sheep)	5*Cydectin Plus Fluke (Fort Dodge Australia) oral liquid for sheep (50 mg TCBZ/ mL//1 mg MOX/mL: 1 mL/ 5 kg b.w.), WT: sheep 21 day	5*: for treatment and control of MOX sensitive GI parasites (incl. BZ and/or levamisole resistant strains), lungworm, TCBZ sensitive strains of liver fluke, and itchmite (<i>Psorergates ovis</i>) of sheep; do not use in female sheep producing or may in the future produce milk or milk products for human consumption; not recommended for use in goats as safety/efficacy has not been evaluated
Albendazole (ABZ) ABZ sulfoxide (7.5–10 cattle) (4–7.5 sheep, lambs, goats)	For detailed information on drug products (incl. other ABZ-combinations), their indications and limitations cf. Nematocidal Drugs, Animals/ Table1	Approved indications: for removal and control of the following internal parasites of cattle and sheep: adult liver flukes (<i>Fasciola hepatica</i> ; also reduces the output of viable worm and fluke eggs), BZ-sensitive mature and immature gastrointestinal roundworms

(Including inhibited type II *Ostertagia* larvae), lungworms, tapeworms; **contraindication:** do not administer BZs within 7 days of a *bromsalans* flukicide because of severe adverse reactions, which result after coadministration of these drugs and which may be fatal in cattle; **experimental studies:** therapeutic activity of ABZ against adult stages of *F. hepatica* (75–100 %) and *Fascioloides magna* (60–99 %) at a single dose of 10 mg/kg b.w. in cattle and 7.5 mg/kg b.w. in sheep

(continued)

Trematodocidal Drugs, Table 1 (continued)

Chemical group international nonproprietary name (INN) (single oral dose, mg/kg body weight = b. w.), other information	*Drug product dose form (formulation), withdrawal time (WT) days (d) before slaughter, manufacturer, supplier, other information	Characteristics: miscellaneous comments on pharmacokinetics, metabolism, mode of action, toxicity, and limitations
is unique among BZs; at latter doses, activity for immature (3–4-week-old stages) <i>Fasciola</i> in cattle is weak (20–25 %) but increased (to 75 %) at higher dosages (50 mg ABZ/kg b.w.); greatest activity against liver fluke infection in sheep has been obtained by using the drug prophylactically (3 mg ABZ/kg b.w. d for 35 days); ABZ is also effective for adult <i>D. dendriticum</i> (7.5–15 mg/kg ×2: weekly interval)		
Albendazole (ABZ)/ closantel (as sodium salt) (CST) (3.8/7.5 sheep)	*Coopers Closal for sheep (Schering-Plough Australia), others, oral liquid (19 gABZ/L//37.5 g CST/L: sheep 1 ml/5 kg b.w.), WT: 28 days	ABZ has been combined with closantel to increase anthelmintic spectrum and efficacy against <i>F. hepatica</i> and <i>Haemonchus contortus</i> ; <i>approved</i>
Indications and limitations: for the control of *Closal susceptible mature and immature GI-roundworms, lungworms (<i>Dictyocaulus filaria</i>), tapeworms (<i>Moniezia</i> spp.), nasal bots (<i>Oestrus ovis</i>), liver fluke, and to reduce the output of viable worm and fluke eggs; for the sustained control of Barber's pole worms (<i>H. contortus</i>) in sheep; do not use in lactating ewes where milk or milk products may be used for human consumption		
Albendazole (ABZ)/ closantel (CST)/ levamisole HCl (LEV)/ abamectin (ABA) (5/7.5/8/0.2 sheep)	*Q-Drench for sheep (Jurox Australia, elsewhere), oral liquid (drench) (25 g ABZ/L//37.5 g CST/L//40 g LEV/L//1 g ABA/L: sheep 1 ml/5 kg b.w.), WT: sheep 28 days	Approved indications and limitations: for the treatment and control in sheep of susceptible GI-roundworms (including strains with single or dual resistance to macrocyclic lactones, BZs, LEV or CST) and strains of Barber's pole worm
(Haemonchus contortus) with emerging resistance to CST; it is also effective against lungworm (<i>Dictyocaulus filaria</i>), tapeworms (<i>Moniezia</i> spp.), mature and late immature liver fluke (<i>F. hepatica</i>), nasal bot (<i>Oestrus ovis</i>), and itch mite (<i>Psorergates ovis</i>); do not use in female sheep, which are producing or may in the future produce milk or milk products for human consumption; do not use in lambs under 6 weeks of age or 10 kg b.w.		
Pyrazinoisoquinolines		
Praziquantel (PZQ): for detailed information on drug products (incl. PZQ-combinations), their indications and limitations cf. Cestodocidal Drugs, and Table 2; primarily active against various cestodes and schistosomes; it also affects <i>D. dendriticum</i> in sheep but efficacy proved erratic (no dose-activity relationship: 98 % efficacy at 20 mg/kg, 76 % at 40 mg/kg, and 98 % at 50 mg/kg; total elimination of flukes was not achieved); infections of dogs with <i>Paragonimus</i> spp. (lung flukes) has been successfully treated with 25 mg/kg b.w. on each of 3 consecutive days; the intestinal fluke <i>Fasciolopsis buski</i> of swine and pancreatic fluke, <i>Eurytrema pancreaticum</i> of sheep, both become eliminated by a single oral dose of 30 and 60 mg/kg b.w., respectively; the skin fluke <i>Gyrodactylus aculeatus</i> of fish can be removed effectively by placing the fish in a water bath for 3 h containing a concentration of 10 mg PZQ/L; it is highly effective against various intestinal flukes in humans (<i>Heterophyes</i> spp., <i>Metagonimus yokogawai</i> and other zoonotic flukes cf. Table 2) and various intestinal flukes of (domestic) animals, including those of fish and reptiles [PZQ-drug products in Australia →*Aquatopia Australia Fluke Eliminator, tablets (100 mgPZQ/Tb: 1 tb/20 L) for fish tank medication: 5 mg PZQ/L controls flukes and tapeworms in ornamental fresh and saltwater aquarium fishes (prohibited for fish intended for human consumption), or *Reptile Science Repti Worm (Universal Manufacturing & Labs, Australia): the combination (50 g fenbendazole/L//5 g PZQ/L: 0.4 mL/kg b.w. per os) controls all important GI-nematodes, lungworms, trematodes (flukes), and cestodes (tapeworms)]		
Halogenated benzenesulfonamides		
In EC, USA, Australia, and elsewhere, clorsulon (CSL) is used for the control of adult liver flukes (<i>Fasciola hepatica</i> and <i>F. gigantica</i>) in cattle only; currently, no drug product containing CSL (incl. clorsulon/ivermectin combination) is commercially available in Germany and elsewhere; however, the clorsulon/ivermectin combination (*Ivomec Plus Biokema SA) is approved for use in beef and dairy cattle in Switzerland (product limitations are similar to those specified by FDA in USA, and a withdrawal time for milk has not been established); neither drug product is approved for use in sheep in EC, USA, Australia and elsewhere; CSL is formulated either as a suspension for oral use (recommended dose: 7 mg/kg b.w. as drench) or an injectable liquid for the subcutaneous route (recommended dose: 2 mg/kg b.w.); the drug combination CSL/ivermectin is frequently used because of its additional effects against important pathogenic nematodes and arthropods

Chemical group international nonproprietary name (INN) (single oral dose, mg/kg body weight = b. w.), other information	*Drug product dose form (formulation), withdrawal time (WT) days (d) before slaughter, manufacturer, supplier, other information	Characteristics: miscellaneous comments on pharmacokinetics, metabolism, mode of action, toxicity, and limitations
--	---	---

in kidney, major component recovered was unchanged drug); **tolerability:** CSL is characterized by low toxicity: studies have demonstrated a wide margin of safety in male fertility and female reproductive performance studies in rodents, rabbits, dogs, and cattle; in two carcinogenicity studies carried out in mice (44, 120, and 306 mg CSL/kg b.w., daily for 2 years) CSL proved not carcinogenic; uninfected sheep tolerated a single oral dose of 200 or 400 mg/kg b.w., and cattle 175 mg/kg b.w. (i.e., 25 times label dosage per os) without adverse reactions (normal weight gain and feed consumption, no clinical signs or histopathologic findings); CSL alone or in combination with IVER are well tolerated by cattle apart from swelling at s.c. injection sites; CSL is considered safe in breeding and pregnant animals provided normal care is taken in handling, CSL is compatible with other anthelmintics

Data of drug products (approved labels) listed in this table refer to information from literature, manufacturer, supplier, and websites such as the European Medicines Agency (EMA), Committee for Veterinary Medicinal Products (CVMP), the US Food and Drug Administration (FDA), Center for Veterinary Medicine (CVM), the Australian Pesticides and Veterinary Medicines Authority (APVMA), and associated Infopest (search for products), VETIDATA, Leipzig, Germany, and Clini Pharm, Clini Tox (CPT), Zurich, Switzerland. Data given in this table have no claim to full information

F. hepatica and young and adult stages of *Paramphistomum* spp. (intestinal flukes), respectively. **Halogenated salicylanilides** that may be regarded as close analogues of the bisphenols with a carboxamide group connecting the two aromatic rings as in case of *bromsalans* (cf. Table 1) were discovered in 1963. Inexpensive bromsalans, which consist of a certain mixture of 3,4', 5-tribromosalicylanilide (tribromosalan, the active principle), and 4', 5-dibromosalicylanilide (dibromosalan, a germicide), may still be used in many countries against mature and immature *Fasciola hepatica* infections in sheep (simultaneous use of benzimidazole with *bromsalans* can cause severe adverse effects and even mortality in cattle); further structural modifications in this group led to a number of modified salicylanilides like *brotianide*, *bromoxanide*, and *clioxanide*; they have been discontinued in most countries (not considered in Table 1). Other salicylanilides such as *oxyclozanide* and *closantel* (cf. Table 1) are still in use; *rafozanide* that has been used in Australia and Europe for a long time is no longer approved in Australia (USA and elsewhere), it is approved in the EC but not commercially available in Germany and elsewhere. Oxyclozanide is only available as combination with levamisole, and closantel may be combined with other nematocidal anthelmintics such as oxfendazole or abamectin; these combinations

are commercially available in Australia and elsewhere. Closantel also provides a sustained control of susceptible Barber's pole worm (*Haemonchus contortus*) infections in sheep. **Bisanilino compounds** initially synthesized as mono- and bisanilino structures in the late 1960s, had caused serious toxic side effects (visual disorders and blindness) in ruminants. Only *diamfenetide* (cf. Table 1), introduced much later in the early 1970s in form of the bisacetylated prodrug, exhibits an excellent activity against immature *F. hepatica* and is tolerated well in sheep. Its rapid deacetylation in the liver leads to the active metabolite whose effectiveness decreases as the flukes grow old (the drug is no longer approved in the USA, Australia, Germany, and elsewhere). **Benzimidazoles** generally affect mature stages of *F. hepatica*; in the USA, *albendazole* (cf. Table 1) is approved as a flukicide, and in Australia it is commercially available as combinations containing closantel and other nematocidal drugs. The excellent flukicide *luxabendazole* (former Hoechst) is no longer available on the Australian market (not considered in Table 1). The chlorinated methylthio-benzimidazole derivative *triclabendazole* has an excellent efficacy against adult stages of *F. hepatica* in cattle and sheep (Table 1); it is also the drug of choice for the treatment of *F. hepatica* infections in humans (cf. Table 2). **Benzene sulfonamides** to be

Trematodocidal Drugs, Table 2 Drugs used against trematode infections of humans

Disease stage(s) of interest (<i>location of stages</i>), other information	International nonproprietary name oral dosage: adult/pediatric (d = days), additional information (*Brand name)	Characteristics of compound, miscellaneous comments
Blood Flukes Schistosomiasis (snail-mediated helminthiasis): statistics about 200 million people are affected with schistosomiasis (120 million: symptomatic, with 20 million having severe clinical disease) worldwide, of whom ~85 % live on the African continent and ~600 million people are at risk [global case fatality rate (infected persons/year) → <i>Schistosoma mansoni</i>: 1–7 %, → <i>S. haematobium</i>: 2 % and → <i>S. japonicum</i> 5 %; global disease burden in 2002 (DALYs): 1,760,000]; infection is caused by cercariae penetrating human skin during contact with freshwater; prevention on an individual level requires that people should avoid any contact with infested freshwater, or that all individuals defecate and urinate in sanitary facilities; at the community level the following control measures should be considered: public health education, sanitation, eradication of snail vector, and chemotherapy; the aim of the chemotherapy is to suppress egg production, which is responsible for pathological damages; early attempts to control the disease (1930–1985) were based on the use of <i>synthetic molluscicides</i> for snail control and drugs such as <i>antimony-based agents</i> and <i>niridazole</i> (Ambilhar) whose efficacy and tolerability was unsatisfactory (reduction in prevalence from 60 % to 30 % at too high cost); since 1975, <i>oxamniquine</i> was used in control programs in Brazil, but in recent years Brazil has switched to using <i>praziquantel</i> (a pyrazinoisoquinoline) as first line drug; over the last 15 years mainly drug treatment programs have reduced serious morbidity caused by schistosomiasis (e.g., bladder cancer in Egypt has declined significantly, as has serious <i>S. mansoni</i>-induced morbidity in Brazil, and <i>S. japonicum</i> morbidity in China); the global distribution of schistosomiasis has changed in recent years; it has been eradicated from Japan and the Lesser Antilles islands; transmission has been interrupted in Tunisia; and transmission is very low in Morocco, Saudi Arabia, Venezuela, and Puerto Rico; current control of schistosomiasis mainly relies on the use of <i>praziquantel</i> (PZQ), the only readily commercially available drug; the original PZQ (*Biltricide) was marketed by Bayer; there are now about 20 pharmaceutical companies formulating PZQ into 600 mg tablets from technical materials produced in South Korea and China; the price/tablet is around US\$ 0.07–0.10; in Egypt a suspension (containing 1,800 mg PZQ/15 mL) is commercially available (price: \$0.90); it was formulated to overcome the bitter taste of the large 600 mg PZQ tablet: treatment in children led to vomiting or reluctance to swallow the tablets; average cost of treatment/child including delivery through a school-based system (schistosome and soil-transmitted helminth infections) is less than \$0.50; PZQ is safe and effective and to date there is little evidence of development of significant resistance; children are particularly vulnerable to schistosomiasis, and infected school-age children are often physically and intellectually compromised by concurrent anemia, attention defects, learning disabilities, and dropout rates; the WHO has generated a strategy whereby most adults and children infected or at risk of developing morbidity will receive PZQ treatment they need [for detailed information cf. http://www.who.int/wormcontrol and Fenwick A et al. (2003), Trends Parasitol 19: 509, or Hagan P. et al. (2004), Trends Parasitol 20: 92]; PZQ has been used extensively and successfully in national control programs in China, the Philippines, Egypt, and Brazil, and treatment programs with PZQ are now expanding in several countries of Africa for more widespread control of schistosomiasis; the market for PZQ was expected to rise substantially towards 40 million tablets a year by the end of 2005 if price can be maintained and resistance is avoided; resistance to PZQ: it may be possible to induce resistance in the laboratory using drug pressure, and thereby prevent or delay emergence of resistance; thus chemotherapy should be targeted only to high-risk groups such as women, fishermen, and school-age children thereby monitoring drug efficacy in operational programs in order to detect first signs of resistance development; to date, no other PZQ-resistant isolates has been identified (in 1992, in Egypt several individuals did not sufficiently respond to PZQ; in 1997, in Senegal patients with extremely high egg counts before treatment showed a certain tolerance to PZQ treatment at regular dose); however, all infected individuals responded to treatment with two or three doses of PZQ; alternative drugs: other drugs, which were used prior to the discovery of PZQ, such as <i>oxamniquine</i> (a tetrahydroquinoline active against <i>S. mansoni</i>) or <i>metrifonate</i> (active against <i>S. haematobium</i>; cf. trichlorfon Nematocidal Drugs Animals/Table 3) are no longer available commercially; consequently, there is a lack of altering drugs in control programs, a classical strategy of avoiding development of drug resistance; several “alternatives” to PZQ are currently discussed and under investigation: (1) development of PZQ analogues but rational approach to new derivatives is hampered by a lack of knowledge as to mechanism of PZQ’s action in vivo – 37 years after its discovery in 1970, (2) the use of malariacidal <i>artemisinin</i> derivatives (e.g., <i>artemether</i>, a methoxy derivative of artemisinin or sesquiterpene lactol, has a good safety profile and is already in use as an antimalarial, cf. (Malariacidal Drugs); earlier studies in golden hamsters demonstrated that artemether interferes with maturation thereby killing larval stages of <i>S. japonicum</i> and <i>S. mansoni</i>; results of another study demonstrated that artemether (1 × 300 mg/kg orally) given at least once every 4 weeks had a preventive effect against <i>S. haematobium</i>, thus providing a basis for testing its ‘prophylactic’ effect in a human population in a highly endemic area; clinical trials in China, Africa and elsewhere corroborate a protective effect of artemether against infections with juvenile stages of <i>S. japonicum</i>, <i>S. mansoni</i>, and <i>S. haematobium</i>; (3) a combination of PZQ and artemether is under evaluation in China, Egypt, the Philippines, and		

(continued)

Trematodocidal Drugs, Table 2 (continued)

Disease stage(s) of interest (<i>location of stages</i>), other information	International nonproprietary name oral dosage: adult/pediatric (d = days), additional information (*Brand name)	Characteristics of compound, miscellaneous comments
other countries; feasibility of this novel control strategy based on experimental trials using animals challenged with <i>S. mansoni</i> and <i>S. japonicum</i> and clinical trials [Utzinger J. et al. (2003) Antimicrob Agents Chemother 47: 1487], and (4) Mirazid (tablets containing 300 mg purified <i>Commiphora</i> extract from the stem of the plant <i>Commiphora molmol</i> or myrrh): when Mirazid was marketed in Egypt, the WHO had been informed; its effect on human schistosomiasis is controversially discussed; it has been reported that myrrh exhibits antischistosomal activity (worm pairs become separated and female worms are shifted to the liver, where they are destroyed); in 1995, raw material was independently tested at laboratories in Brazil and the USA, and in vitro no antischistosomal activity was found; Mirazid's label claims "amelioration of all symptoms within 1 week" but original claims published might be difficult to reproduce; enantiomers of PZQ: PZQ is currently marketed as a chiral molecule, i.e., standard preparations are composed of equal proportions of the active, levo (–) and the inactive, dextro (+) optical isomers; the activity of the (–) enantiomer has been established in experiments performed both in vivo and in vitro; thus, the production of PZQ as a single active form would halve the therapeutic dose and possibly minimize adverse effects of the drug; however, methods (selective synthesis, or industrial chromatography) that could achieve production of levo-PZQ would drastically increase cost and might be an uneconomic exercise; characteristics of PZQ: usually well tolerated; mechanism of action is complex and is apparent in damage of the worm's tegument membrane; exposure of such damaged integument to the host's immune system induces inflammatory reactions, which lead to worm's death; cure rate is equal to or greater than 85 %; in persons not cured, the egg burden is markedly decreased; contraindications: documented hypersensitivity and ocular cysticercosis; destruction of parasite within the eyes can cause irreparable lesions; therefore, ocular cysticercosis must not be treated with PZQ (cf. Cestodocidal Drugs); interactions: <i>hydantoins</i> may reduce serum praziquantel concentrations, possibly leading to treatment failures; pregnancy: usually safe but benefits must outweigh the risks; precautions: caution while driving or performing other tasks requiring alertness on the day of and following treatment; minimal increases in liver enzymes reported; when schistosomiasis or fluke infection is associated with cerebral cysticercosis, patient should be hospitalized for duration of treatment; characteristics of oxamniquine (e.g., *Vansil Pfizer, drug is no longer available commercially in the USA and elsewhere): mechanism of action is complex: the <i>tetrahydroquinoline</i> is metabolized into an ester by schistosomes which may damage tegument surface of male schistosome worms so that the immune system is able to kill the worm; drug has action on reproductive processes thereby inhibiting female worms from producing eggs; drug is only effective against <i>S. mansoni</i> (cure rates: 70–90 %); contraindications: documented hypersensitivity and pregnancy (unsafe); interactions: none reported but food may delay absorption; precautions: use caution and closely monitor in patients with history of seizures because they may experience epileptiform convulsions; EEG abnormalities may develop in patients with normal pretreatment recordings <i>Schistosoma mansoni</i> adults (<i>venous system of intestine</i>), eggs (embryonated, large, oval, with lateral spine, pass into feces; the latter must be deposited in fresh water so that miracidia can hatch and reach appropriate snails), endemic in Africa, Middle East, and parts of South America; intestine and liver are primarily affected; eggs (soluble antigens in tissues) induce severe inflammatory reactions related to intensity of infection and so host response; damage caused in acute phase is followed by irreversible fibrosis of liver and adjacent tissues	Drug of choice: praziquantel (PZQ) (e.g., *Biltricide Bayer, others) (40 mg/kg/day in 2 doses × 1 day: adult/pediatric) alternative: oxamniquine (15 mg/kg once, pediatric 20 mg/kg/day in 2 doses × 1 day adult/pediatric: in East Africa, the dose should be increased to 30 mg/kg, and in Egypt and South Africa to 30 mg/kg/day × 2 days; some experts recommended 40–60 mg/kg over 2–3 days in all Africa [Shekhar KC (1991) Drugs 42: 379]	PZQ is (was) a major therapeutic breakthrough in control of schistosomiasis (cure rates 85–100 %); side effects are common and mild: headache, diarrhea, rash, fever; single dose treatment results in a very high cure rate; <i>levo</i>-PZQ (150 mg/kg b.w.) administered to mice infected with <i>S. mansoni</i> caused damage to the tegument of adults including severe swelling, vacuolization, fusion of the tegumental ridges, and loss or shortening of the spines on the tubercles, collapse, and peeling (<i>dextro</i> PZQ proved inactive) <i>oxamniquine</i> (*Vansil Pfizer) (regional differences in efficacy,
Cure rates 70–90 %) has been used in areas in which PZQ is less effective; it has no useful efficacy against <i>S. haematobium</i> and <i>S. japonicum</i>; side effects are common but mild; in rare cases convulsions (history of epilepsy), and minor increase of transaminase activities; its use is contraindicated in pregnancy. and safety has not been established in young children

Trematodocidal Drugs, Table 2 (continued)

Disease stage(s) of interest (<i>location of stages</i>), other information	International nonproprietary name oral dosage: adult/pediatric (d = days), additional information (*Brand name)	Characteristics of compound, miscellaneous comments
<i>S. japonicum</i> adults (<i>mesenteric venules</i>), eggs (embryonated, large but smaller than those of <i>S. haematobium</i> , globular, lack a spine, pass into feces; eggs must be deposited in fresh water so that miracidia can hatch and reach appropriate snails) endemic in the	<i>Drug of choice: praziquantel</i> (PZQ) (60 mg/kg in 3 doses $\times$ 1 day: adult/pediatric); <i>artemether</i> (*Artemam Arenco) [field trials (>4,500 individuals) conducted in China among high-risk groups have shown that artemether is a promising drug against schistosomula at oral	Cure rates of PZQ may be 80–92 %; generally a single dose of PZQ has the same efficacy as several smaller doses given at intervals of several hours but frequency of side effects is greater with a large single PZQ dose; tissue damages induced by <i>S. japonicum</i> is more severe than those caused by <i>S. mansoni</i>
Far East, SE Asia, Philippines; acute systemic reactions (Katayama fever); chronic stage of disease with hepatomegaly caused by portal fibrosis, and splenomegaly; liver is the organ most affected (fatal fibrosis)	Doses of 6 mg/kg b.w./day given in 15-day-intervals $\times$ 4]	(For diagnostic problems cf. <i>S. mekongi</i> ↓); over the last 25 years, researchers from China [cf. Xiao SH (2005) Acta Trop 96: 153] successfully developed <i>artemether</i> and <i>artesunate</i> (Guilin No.1 Factory China),
Two derivatives from the antimalarial artemisinin, as promising drugs against <i>S. japonicum</i> ; laboratory investigations showed that the artemisinins display their highest activity against the juvenile stages of the parasite; thus <i>artemether</i> (3 $\times$ 15 mg/kg per os given on d7/d14/d21 after infection) exhibited 93–98 % efficacy against schistosomula (juvenile flukes) in rabbits and dogs infected with cercariae of <i>S. japonicum</i> ; these findings were consistently confirmed in randomized controlled trials in humans; repeated oral administration of artemether or artesunate was safe and efficacious in the prevention of patent <i>S. japonicum</i> infections; <i>Schistosoma</i> species are sensitive to artemether medication for slightly different lengths of time: <i>S. japonicum</i> is susceptible up to 21 days of age, while <i>S. mansoni</i> responds to the drug for up to 42 days of age, and <i>S. haematobium</i> , due to the longer time it takes to develop into adults, has an even longer period of sensitivity; in areas that are endemic for both malaria and schistosomiasis, the use of artemether is precluded because of the possibility that its regular use might contribute to the development of resistance of the malaria parasite; on the other hand, the drug could safely be recommended for use in schistosomiasis in areas where there is no regular malaria transmission (e.g., in China, southern Brazil, countries north of the Sahara, parts of the Middle East); of particular interest are those areas where human schistosomiasis has been very much reduced, but final eradication has proved difficult (e.g., in Saudi Arabia, Morocco), where artemether could contribute to breaking its transmission; it could also play an important role in the control of schistosomiasis in Egypt		
<i>S. mekongi</i> adults (<i>mesenteric venules</i>), eggs (resemble closely <i>S. japonicum</i> eggs) pass into feces; “minor” species in Southeast Asia	<i>Drug of choice: praziquantel</i> (PZQ) (60 mg/kg in three doses $\times$ 1 day: adult/pediatric)	Endemic along Mekong river, including Laos, Cambodia, Thailand) diagnostic problems: fecal debris adheres to shell of <i>S. japonicum</i> and <i>S. mekongi</i> eggs; thus eggs may be overlooked in fecal preparations (spine is inapparent and difficult to see)
<i>S. intercalatum</i> adults (<i>mesenteric venules</i>), eggs (resemble closely <i>S. haematobium</i> eggs but are larger) pass into feces	<i>Drug of choice: praziquantel</i> (PZQ) (60 mg/kg in three doses $\times$ 1 day: adult/pediatric)	<i>S. intercalatum</i> (a “minor” species of man in West and Central Africa) <i>S. bovis</i> , <i>S. mattheei</i> or <i>S. nasalis</i> are primarily parasites in other mammals (e.g., equines, ruminants), and may infrequently infect humans
<i>S. haematobium</i> adults (venous plexus of urinary tract mainly bladder), eggs (embryonated, large oval, with terminal spine pass into urine; latter must be deposited in fresh water so that miracidia can hatch and reach appropriate snails);	<i>Drug of choice: praziquantel</i> (PZQ) (e.g., *Biltricide Bayer, others) (40 mg/kg/day in two doses $\times$ 1 day: adult/pediatric), considered safe in children over 4 years of age who tolerate it better than do adults (contraindications: ocular	Single dose treatment results in a cure rate equal to or greater than 85 %; in persons not cured, the egg burden is markedly decreased; side effects caused by PZQ are common but mild such as nausea, abdominal discomfort, dizziness, headache, and diarrhea; rash, pruritus, urticaria,

(continued)

Trematodocidal Drugs, Table 2 (continued)

Disease stage(s) of interest (<i>location of stages</i>), other information	International nonproprietary name oral dosage: adult/pediatric (d = days), additional information (*Brand name)	Characteristics of compound, miscellaneous comments
endemic in 54 countries of Africa and the eastern Mediterranean	cysticercosis cf. general information on schistosomiasis†)	fever; myalgia and eosinophilia are noted occasionally and are related to parasite burden
(Inflammatory reactions); high doses of PZQ do increase abortion rates in rats, so drug probably is best avoided during first trimesters of human pregnancy; relatively inexpensive <i>metrifonate</i> (syn trichlorfon, e.g., *Neguvon Bayer cf. Nematocidal Drugs, Animals), an organophosphate (5–10 mg/kg b.w. ×3 at 2 week intervals) may be still used concurrently with <i>oxamniquine</i> (*Vansil Pfizer, contraindicated in pregnancy) for the treatment of mixed infections with <i>S. haematobium</i> and <i>S. mansoni</i>; the drug has no useful effects against other schistosome species; <i>niridazole</i> (earlier *Ambilhar: 25 mg/kg b.w., maximum 1.5 g/day, for 7 days), a 5-nitrothiazole, is no longer in use because of serious adverse effects it had caused in patients with CNS and/or hepatic disorders exaggerating typical symptoms like confusion, hallucinations, convulsions, and metabolic imbalance; it was used also in <i>Dracunculus medinensis</i> (Guinea worm) infections (cf. Nematocidal Drugs, Man); <i>disease pattern</i> of <i>S. haematobium</i> infection primarily involves the lower genitourinary tract; urinary bilharziasis is characterized by hematuria, obstruction of ureters, and hydronephrosis; in chronic infections, accumulation of eggs around the bladder and Ureters results in severe inflammation of bladder and adjacent tissues (organs), which may involve the kidneys (pyelonephritis); the extent of granuloma formation (around eggs) and following fibrosis of affected tissues generally correlate with the intensity of infection; in untreated patients, the bladder epithelium can transform into squamous cell <i>carcinoma</i> occurring usually 10–20 years after the initial infection; in addition, immune complexes that contain egg antigens may deposit in the glomeruli, leading to glomerulonephritis and amyloidosis Intestinal Flukes (more than 50 hermaphroditic species exist) infections are acquired by consumption of littoral vegetation, raw or undercooked fish, or mollusks contaminated/infected with encysted cercariae (metacercariae); only a few species cause infection in humans, and the most common human intestinal trematode is <i>Fasciolopsis buski</i> (~15–20 million infected people in areas of the Far East, cercariae encyst on aquatic plants); metacercariae of <i>Echinostoma ilocanum</i> encyst in freshwater mollusks (primarily snails or clams), and metacercariae of <i>Heterophyes heterophyes</i> (~10 million infected people, uncommon but widely distributed) and those of <i>Metagonimus yokogawai</i> (most common heterophyid fluke in areas of the Far East and Mediterranean basin) encyst under the scales or in the skin of various brackish or freshwater fish; common symptoms caused by these small digeneans armed with spines, such as heterophyids are dependent on worm burden present; in heavy infections with thousands of worms occlusion of common bile duct and small intestine can occur and then individuals develop a nonspecific diarrhea and experience abdominal pain similar to that due to peptic ulcer; eosinophilia is a common feature; rarely, the small heterophyids (<i>H. heterophyes</i>: 1–1.8 mm in length and 0.3–0.7 mm in width) and their eggs tend to form clots (emboli) traveling via the circulation to aberrant sites of the body causing fatal pathological alterations (cf. Trematode Infections of humans ↓); the primary <i>control measure</i> against infections with intestinal flukes (transmission of eggs to intermediate hosts) is prevention of contamination of water supplies with fecal material; reservoir hosts like fish-eating mammals may also play a role in the maintenance of intestinal trematodes in the environment		
<i>Nanophyetus salmincola</i> adults (<i>small or large intestine</i>), eggs (unembryonated, indistinct operculum, much smaller than those of <i>P. westermani</i>) pass into feces; it occurs in eastern Siberia, Northwestern of USA	<i>drug of choice</i> : praziquantel (PZQ) (e.g., *Biltricide Bayer, others) (60 mg/kg in three doses × 1 day: adult/pediatric)	Fluke infects various <i>fish-eating animals</i> (dog, cat, fox otter mink, lynx, and some piscivorous birds, including man) cercariae emerge from snail, come in contact with fish (family Salmonidae) and encyst under scales; man becomes infected by ingestion of raw or undercooked fish or via contaminated
Utensils, hands and surfaces used first to prepare fish or vegetables for cooking or other foods taken raw; the fluke penetrates deeply into the mucosa of the duodenum or attaches to the mucosa of other parts of the small and large intestine thereby causing superficial or hemorrhagic enteritis; adult <i>N. salmincola</i> may harbor <i>rickettsial</i> organisms causing an often fatal disease in dogs or other Canidae (so-called “salmon poisoning,” and “Elokomina fluke fever” may cause high morbidity); <i>N. salmincola</i> and lung flukes (<i>Paragonimus</i> spp.↓) belong to the same family (Troglotrematidae)		
Heterophyiasis		

(continued)

Trematodocidal Drugs, Table 2 (continued)

Disease stage(s) of interest (<i>location of stages</i>), other information	International nonproprietary name oral dosage: adult/pediatric (d = days), additional information (*Brand name)	Characteristics of compound, miscellaneous comments
<i>Heterophyes heterophyes</i> adults (attached to wall of <i>small intestine</i>), eggs (small, embryonated inconspicuous operculum, egg resembles that of <i>C. sinensis</i>) pass into feces	<i>Drug of choice: praziquantel</i> (PZQ) (75 mg/kg in three doses $\times$ 1 day: adult/pediatric)	Small intestinal fluke, which is uncommon but widely distributed (Middle East, Turkey, eastern and southeastern Asia); it occurs in dog, cat, fox, and man; many species of fish (brackish or freshwater fish) act as second intermediate host; only heavily infected individuals may show nonspecific diarrhea, abdominal pain, and eosinophilia
Metagonimiasis		
<i>Metagonimus yokogawai</i> adults (attached to wall of small intestine), eggs (embryonated, small, egg resembles that of <i>C. sinensis</i> and <i>Heterophyes</i> but it has an obvious operculum)	<i>Drug of choice: praziquantel</i> (PZQ) (75 mg/kg in three doses $\times$ 1 day: adult/pediatric)	Small intestinal fluke; most common heterophyid fluke in the Far East (also found in Mediterranean basin); it may occur in dog, cat, pig, and man; several species of freshwater fish act as second intermediate host; only heavily infected individuals may develop nonspecific diarrhea and vague abdominal complaints
Echinostomatiasis		
<i>Echinostoma ilocanum</i> <i>E. lindoense</i> , <i>E. hortense</i> adults (attached to wall of <i>small intestine</i>), eggs (usually large, oval, unembryonated)	<i>Drug of choice: praziquantel</i> (PZQ) (e.g., *Biltricide Bayer, others) (75 mg/kg in three doses $\times$ 1 day: adult/pediatric)	Are primarily parasites of birds and rodents; <i>E. ilocanum</i> may be common in humans (Korea, Philippines, Indonesia) whereas <i>E. hortense</i> is principally a parasite of rodents; same snail or neighboring snails (some
Echinostomatids: fish, clams, and tadpoles) also serve as second intermediate host; mild infections are asymptomatic but heavy infection can be accompanied with diarrhea, and intestinal colic (similar to fasciolopsiasis)		
Gastrodisciasis		
<i>Gastrodiscoides hominis</i> adults (attached to wall of <i>colon</i> and <i>cecum</i>), eggs (unembryonated, large, ovoid, egg resembles closely to that of <i>F. hepatica</i> or <i>F. buski</i>)	<i>Drug of choice: praziquantel</i> (PZQ) (75 mg/kg in three doses $\times$ 1 day: adult/pediatric)	Occurs in India southeast Asia and parts of the former USSR; pigs (natural host), monkeys and man, field rats serve as hosts; incorrect egg diagnosis may occur; man acquired infection by eating uncooked aquatic plants; only a massive infection may produce mucous diarrhea
Fasciolopsiasis		
<i>Fasciolopsis buski</i> adults (~7.5 cm long, 2 cm wide, attached to wall of <i>small intestine</i>), eggs (unembryonated, large, broadly ellipsoidal, operculum indistinct; egg resembles closely to that of <i>F. hepatica</i>)	<i>Drug of choice: praziquantel</i> (PZQ) (75 mg/kg in three doses $\times$ 1 day: adult/pediatric)	Large intestinal fluke that occurs in Far East (India, China, Taiwan, Thailand, Indonesia, and other parts of Asia); fresh water snails serve as intermediated hosts; mature cercariae emerge from snail, attach to aquatic plants (water
Caltrop, water bamboo, water chestnut, lotus on the roots, and other aquatic vegetables) and encyst to become metacercariae; man becomes infected by ingestion of uncooked vegetation contaminated with metacercariae; in severe infections (thousands of worms), flukes may also attach to the ileum or colon; intestinal flukes cause inflammation, ulceration, and mucous secretion at the site of attachment; symptoms may be eosinophilia, diarrhea, and edema, severe		

(continued)

Trematodocidal Drugs, Table 2 (continued)

Disease stage(s) of interest (<i>location of stages</i>), other information	International nonproprietary name oral dosage: adult/pediatric (d = days), additional information (*Brand name)	Characteristics of compound, miscellaneous comments
infections may also cause intestinal obstruction or malabsorption leading to hypoalbuminemia, ascites, and obstruction of common bile duct; pigs are an important reservoir host		
Liver flukes		
Infections are acquired from consumption of raw or undercooked fish or crustaceans infected with encysted metacercariae, or from ingestion of raw or undercooked plants contaminated with metacercariae; <i>Fasciola</i> infections are rare but globally widespread: a total of ~2,600 cases of human <i>F. hepatica</i> has been reported in the UK, France, Spain; Portugal, Tadjikistan, Egypt, Peru, Cuba between 1970 and 1990, and some cases of human <i>F. gigantica</i> infection has been reported in Africa, Asia, Hawaii, former USSR, Vietnam, and Iraq		
FASCIOLIASIS is a major public health problem in several areas of the world, including the highlands of Bolivia, Ecuador and Peru, the Nile Delta in Egypt, and Central Vietnam; it is estimated that at least 2.4 million people are infected (more than 180 million at risk of infection: Report of WHO informal meeting on use of triclabendazole on fascioliasis control, Geneva 2006)		
<i>Fasciola hepatica</i> , <i>F. gigantica</i> adults (2.5–5 cm long, 0.6–1.4 cm wide, <i>F. gigantica</i> up to 7.5 cm long: both flukes live in bile ducts, liver tissue, and aberrant sites, e.g., lung and/or subcutaneous tissue), eggs [unembryonated, large, broadly ellipsoidal, operculum indistinct; shape of egg (both species) resembles closely to that of <i>F. buski</i> and pass into feces] cosmopolitan distribution, closely related flukes of herbivores and other mammals, rarely man; if no eggs are found (aberrant sites) serological tests	Drug of choice: triclabendazole (a benzimidazoles) (TCBZ) (*Egaten, Novartis) (10 mg/kg once or twice: adult/pediatric) [Richter J et al. (2002) Curr Treat Option Infect Dis 4: 313] (cf. characteristics of TCBZ in animals Table 1 ↑) alternative: bithionol (a bisphenols) (*Bitin, Tanabe, Japan) (30–50 mg/kg on alternate days × 10–15 doses: adult/pediatric) (<i>praziquantel</i> proved ineffective against <i>Fasciola</i>) TCBZ: there may be availability problems or it is	Aquatic snails (<i>Lymnaea</i> spp.) serve as intermediate hosts; infection is acquired by ingestions of encysted cercariae (metacercariae) attached to wet grass and herbs (e.g., watercress); adults of <i>Fasciola hepatica</i> (global distribution, most common in sheep and cattle, wild ruminants, but also dog, cat, swine, horse, kangaroo, man) and <i>F. gigantica</i> (throughout Asia, Middle East, Africa, the Americas, and Hawaii, most common in cattle) borrow tunnels through the liver parenchyma and feed on hepatocytes and blood; they produce
(E.g., ELISA) may be positive during acute phase of infections; recent experimental results with artemisinin derivatives are encouraging	Available only from the manufacturer, e.g., in the USA and elsewhere	Inflammation reactions leading to fibrosis of adjacent tissues in chronic infections; symptoms in humans are malaise, intermittent fever, pruritus, eosinophilia, abdominal pain,
Jaundice, enlarged liver, anemia, aberrant adults (e.g., subcutaneous tissue) may be removed surgically most common adverse reactions of TCBZ in patients with acute/chronic disease are biliary colic, nausea, anorexia, vomiting, pruritus, jaundice (for details cf. http://www.who.int/neglected_disease/preventive_chemotherapy/WHO_CDS_NTD_PCT_2007.1.pdf)		
Small Liver Flukes (adult worms are flattened and spatulate (1–2.5 cm long, 3–5 mm wide) most food-borne trematodes are zoonotic (parasites of nonhuman animals), which “accidentally” infect humans; there are several species, e.g., <i>Dicrocoelium</i> , <i>Opisthorchis</i> , or <i>Clonorchis</i> , which infect livestock and mammalian wildlife and have been reported to be endemic in several countries [total number of human liver fluke infections is estimated ~30 million worldwide: <i>Clonorchis</i> ~19 million (e.g., India, China, Taiwan, Korea, Southeast Asia: Vietnam, Laos, Cambodia, other countries), <i>O. viverrini</i> ~9 million (Thailand, Laos), and <i>O. felineus</i> ~1.5 million, (Russian Federation, Eastern Europe)]; eggs of these genera are very similar in shape (and color) and are difficult to differentiate and may be sometimes confused with heterophyid eggs but generally are somewhat larger and may have a seated operculum; obligate intermediate hosts are snails and other invertebrates (e.g., <i>Dicrocoelium</i> : nonaquatic snails and ants); biology, pathogenesis, and clinical disease caused by <i>Opisthorchis</i> and <i>Clonorchis</i> are largely identical		
<i>Dicrocoelium dendriticum</i> adults (fine branches of bile ducts, gallbladder), eggs (embryonated, ovoid, small, indistinct operculum, brown shell) pass into feces; is	<i>Praziquantel</i> , or <i>albendazole</i> (may be effective at dose regimens recommended for other small liver flukes, cf. <i>Clonorchis sinensis</i> and <i>O. viverrini</i>)	Infections in man are rare but globally widespread, cf. <i>F. hepatica</i> ↑), not as pathogen as <i>F. hepatica</i> ; intermediate (IM) hosts are land snails (first IM) and ants (second IM);

(continued)

Trematodocidal Drugs, Table 2 (continued)

Disease stage(s) of interest (<i>location of stages</i>), other information	International nonproprietary name oral dosage: adult/pediatric (d = days), additional information (*Brand name)	Characteristics of compound, miscellaneous comments
cosmopolitan in herbivores, rabbit, pig, dog, deer)		infection is acquired by ingestions of ants; in advanced cases extensive cirrhosis of liver, clinical signs may be anemia, edema, and emaciation
Clonorchiasis		
<i>Clonorchis sinensis</i> (Chinese or oriental liver fluke) adults (bile ducts, some-times pancreatic duct and duodenum) eggs (embryonated, ovoid, small, seated operculum) pass into feces occur in Japan, Korea, Vietnam and China	<i>Drug of choice: praziquantel</i> (PZQ) (75 mg/kg in three doses × 1 day: adult/pediatric) or albendazole (*Albenza or *Eskazole GlaxoSmithKline) (10 mg/kg × 7 days: adult/pediatric)	Fish-eating mammals (e.g., weasel, mink, dog, cat, pig, rats) serve as reservoir hosts; adult worms may live in host for up to 25 years; cercariae emerge from snail, come in contact with fish and encyst under scales; man becomes infected by ingestion of raw or
Undercooked <i>freshwater fish</i> (Cyprinidae: ~100 species of cyprinoid fish serve as second intermediate host of <i>Clonorchis</i> or <i>Opisthorchis</i>); such fish is prepared in many different ways depending on cultural, nutritional, and medicinal habits (e.g., marinating raw fish in various sauces and dipping in rice porridge or kongee, or beliefs that consumption of alcohol will kill the parasites); transmission can also occur via contaminated utensils, hands, and surfaces used first to prepare fish or vegetables for cooking or other foods taken raw, or by imported <i>pickled fish</i> containing viable metacercariae, which may lead to human infections in countries where <i>Clonorchis</i> and <i>Opisthorchis</i> do not occur; only heavy infections are clinically significant caused by obstructive liver disease and inflammatory gallbladder pathology (stones: hepatolithiasis); symptoms may be diarrhea, abdominal pain, icterus; ascites resulting from cirrhosis of liver; in severe chronic infection <i>cholangiocarcinoma</i> of the liver may develop; <i>C. sinensis</i> infection was judged a <i>probable carcinogen</i> [International Agency for Research on Cancer (Lyon 1994) schistosomes, liver flukes, and <i>Helicobacter pylori</i> . IARC Monographs on the evaluation of carcinogenic risks to humans, 61: 121–175]		
Opisthorchiasis <i>O. viverrini</i> infection was classified as a <i>human carcinogen</i> (IARC 1994, for literature cf. <i>Clonorchis sinensis</i> ↑)		
<i>Opisthorchis felineus</i> (syn. <i>O. tenuicollis</i>); <i>O. viverrini</i> , (southeast Asian liver fluke) <i>Metorchis conjunctus</i> (North American liver fluke); adults (gall bladder, bile ducts of liver), eggs (embryonated, small, seated (or small: <i>Metorchis</i>) operculum, difficult to distinguish from those of <i>C. sinensis</i>) pass into feces	<i>Drug of choice: praziquantel</i> (PZQ) (e.g., *Biltricide Bayer, others) (75 mg/kg in three doses × 1 day: adult/pediatric) <i>mebendazole</i> (has been reported to be effective)	<i>Distribution and reservoir hosts</i> of closely related liver flukes: <i>O. felineus</i> (Russian Federation, Eastern Europe; cats, civets, dogs, pigs, rats, other mammals, and man), <i>O. viverrini</i> (northern Thailand, and Laos; dog, cat, fox, pig, endemic in man), <i>M. conjunctus</i> (areas of northern America; dog, cat fox, mink, raccoon, other wildlife, man); <i>M. albidus</i> (Europe,
Former parts of the USSR, and North America, cyprinid fish serve as second intermediate hosts; dog, cat, fox, mink, raccoon, other wildlife, man); humans become infected by ingestion of raw or undercooked cyprinoid freshwater fish (details concerning transmission of <i>Opisthorchis</i> and <i>Metorchis</i> infection to man including pathogenesis, pathologic alterations, and clinical signs cf. <i>Clonorchis sinensis</i> ↑; disease pattern of small liver flukes is very so similar that separate description is unnecessary)		
Lung Flukes: some 16 species of the <i>Paragonimus</i> genus cause human paragonimiasis, the most common cause being the “Oriental lung fluke,” <i>Paragonimus westermani</i> ; genera <i>Nanophyetus salmincola</i> (cf. intestinal fluke) and <i>Paragonimus</i> belong to the same family (Troglorematidae); infections are often due to cultural-specific habits of minorities and aboriginal people, i.e., consumption of raw or undercooked freshwater crustaceans (crabs, crayfish) infected with metacercariae		
Paragonimiasis		
Asia: <i>Paragonimus westermani</i> <i>P. heterotremus</i> , <i>P. skrjabini</i> Africa: <i>P. uterobilateralis</i> , <i>P. africanus</i> Canada: <i>P. kelliottii</i> Peru, Ecuador:	<i>Drug of choice: praziquantel</i> (PZQ) (e.g., *Biltricide Bayer, others) (75 mg/kg in three doses × 2 days: adult/pediatric); PZQ is better	Human lung flukes may infect an estimated 21 million people worldwide (~10 million in China: Asiatic species), <i>Paragonimus</i>

Trematodocidal Drugs, Table 2 (continued)

Disease stage(s) of interest (<i>location of stages</i>), other information	International nonproprietary name oral dosage: adult/pediatric (d = days), additional information (*Brand name)	Characteristics of compound, miscellaneous comments
<i>P. mexicanus</i> adults/**larvae (forming cysts, capsules in lung parenchyma; **aberrant sites: brain, spinal cord, peritoneum, liver, spleen, kidneys, testes/ovary, muscles, intestinal wall, mesenteric lymph nodes, s.c. tissue) eggs (unembryonated, prominent operculum, different sizes: <i>P. westermani</i> much larger than others, dark shell) pass up from lung into sputum (eggs: either dislodged by coughing or swallowed and pass into feces); eggs can be confused with smaller cestode eggs of <i>Diphyllbothrium latum</i>	tolerated than bithionol; PZQ is contraindicated in ocular disease alternative: bithionol (*Bitin Tanabe, Japan) (30–50 mg/kg on alternate days × 10–15 doses: adult/pediatric) (*availability problems) Surgical: excision of extra-pulmonary lesions, shunt in case of hydrocephalus	infections being endemic in central China, Philippines, Thailand, Korea, Laos, and found in Taiwan, Japan, Malaysia, Indonesia, and India; other species cause infections in Asia and the Pacific, Africa, Canada, Central and South America (scattered reports); lung flukes are common in <i>crustacean-eating</i> wild carnivores (e.g., otter, fox, mink, mongoose, dog, cat, wildcat, raccoon, tiger, leopard, panther, wolf, and omnivores like bush rat, rat, pig, monkeys, and other mammals including man; <i>transmission</i>: humans acquired infection by ingestion of raw undercooked <i>crabs</i> or <i>crayfish</i> (second intermediate hosts containing encysted

Cercariae or metacercariae in the viscera, muscles or gills) in form of uncooked paste and other prepared crab food (e.g., strips of raw crab meat soaked in rice wine: “drunken crab” in China, raw crab/crayfish plus alcohol in the Philippines, seasoned raw crab “Gye muchim” in Korea, raw prawn “ama ebi,” sushi crab, and others in Japan); *symptoms*: slight infection is asymptomatic; during acute phase (invasion and migration of immature stages may last several weeks): urticaria, diarrhea, abdominal pain followed by fever, sweats, chest pain, cough, dyspnea, and malaise; *pulmonary symptoms* (~6 months postinfection) resemble a chronic bronchitis or *tuberculosis* (dry cough, dyspnea, chest pain, production of tenacious and rusty or golden sputum); *pathogenesis*: soluble antigens and metabolic products of worms/eggs may cause inflammatory reactions in lungs as fibrotic lesions, hyperplasia of bronchioles, bronchiectasis, and interstitial/bronchopneumonia, and rarely pneumothorax (communicating capsules may cause bacterial superinfection leading to lung abscesses, pleural effusion, or empyema, especially in untreated cases); in chronic infection clubbing of fingers and toes may occur; migrating worms or eggs lodge in other organs (cf. left column: aberrant sites ↑) may cause cysts, abscesses, or granulomas; *cerebral infection* (<1 % of patients, more common in children) resembles cysticercosis, and epilepsy being a frequent manifestation; brain lesions produce seizures, facial palsy, hemiplegia, and paraplegia; ocular disease can impair visual acuity because of optic atrophy, papilledema, and hemianopsia (loss of vision in one half of one or both eyes’ visual field); *diagnostic tests*: serology: ELISA; immunoblot, intradermal, others; *imaging*: CXR (= chest x-ray), CT/MRI (= magnetic resonance imaging) or ultrasound scans, or lumbar puncture, pleural aspiration, and lung biopsy

Dosages listed in the table refer to information from manufacturer, literature, websites (WHO), and Medical Letter (2004) *Drugs for parasitic infections*’ volume 46 (issue 1198): e1–e12. New Rochelle New York. Additional information on trematodocidal drugs used in veterinary medicine (drug products, manufacturers and suppliers, biological characteristics and adverse effects of drugs) cf. “Trematodocidal Drugs”↑ (general consideration: text and Table 1)

Data given in this Table have no claim to full information

subjected to extensive modification in a series of halogenated sulfanilamide derivatives led to *clorsulon* (cf. Table 1) in the late 1970. It is approved in the USA and elsewhere for the oral and parenteral treatment of immature and adult liver fluke infestations in cattle removing all adult stages of *F. hepatica* at recommended doses. The drug is safe for use in breeding and

pregnant animals; it is frequently used as combination with *ivermectin* exhibiting high efficacy against important pathogenic nematodes and arthropods.

Side effects, limitations and drug resistance: In general, side effects due to flukicides are negligible (occasionally loosening of feces); only some older halogenated hydrocarbons may rarely show

erratic toxicity including mortality. At recommended dose, the majority of therapeutic indices of current flukicides seem to be safe for ruminants (e.g., halogenated phenols: 1–4, diamfenetide: 3–5, salicylanilides: 4–6, clorsulon: 5, triclabendazole: 20–40). *Limitations* of flukicide products (cf. Table 1) specified for meat and milk producing cattle and sheep are due to the wide range of preslaughter withdrawal (withholding) periods depending on their pharmacokinetic properties (terminal half-life and resulting residues in edible tissues after treatment). Thus some salicylanilides as closantel and rafoxanide showing additional activity against *H. contortus* are bound extensively to plasma proteins (mainly to albumin) resulting in long terminal half-lives in sheep and cattle. *Drug resistance* in *F. hepatica* to various flukicides (rafoxanide, closantel, and triclabendazole) has been identified in endemic areas of Australian sheep farms and other countries with extensive grassland husbandry in the early 1990s and has become an increasing problem. The long and regular use of salicylanilides, particularly rafoxanide, and closantel but also the benzimidazoles triclabendazole and albendazole support the selection of drug-tolerant field strains of this fluke. Several drug combinations, actually used in Australia and elsewhere may slow down the development of further spreading of drug-tolerant *F. hepatica*. The application of such drug combinations may be indicated if one partner of the combination has developed reduced efficacy and the counterpart is still fully active against *F. hepatica* field strains.

Pyrazinoisoquinolines first synthesized and modified for their pharmacological activities had their major breakthrough with the discovery of the cestodocidal activity of praziquantel (PZQ) in the early 1970s (cf. ► **Cestodocidal Drugs**). Early reports on the efficacy of PZQ against various schistosome species in mice, hamsters, and nonhuman primates were soon followed by reports of high efficacy in man in 1979. In time, it turned out that PZQ was highly active against all pathogenic trematodes with the exception of *F. hepatica*. The absence of morphological PZQ effects in *Fasciola* may be attributable to the

thickness of the tegument (up to 22 μm , versus 1–3 μm in *Schistosoma*) and the high content of fortifying fibrils. Also, the molecular mode of action of these two trematodes may be significantly different. PZQ removes adult stages of *D. dendriticum* (erratic effect) and the pancreatic fluke *Eurytrema pancreaticum* in sheep, adults of *Paragonimus* sp. in dogs and *Fasciolopsis buski* in swine; it also kills the skin fluke *Gyrodactylus aculeatus* of fish and other piscivorous parasites such as intestinal flukes and cestodes (cf. Table 1). PZQ affects the adult stages of zoonotic and nonzoonotic *Schistosoma* spp. in cattle thereby producing large numbers of killed worm pairs and thus portal obstruction with more serious consequences than the disease itself. It is the current drug of choice for the treatment of human schistosomiasis (cf. Table 2) caused by bloodflukes such as *S. mansoni*, *S. haematobium*, or *S. japonicum*, and other human trematode infections due to small liver flukes (*Clonorchis*, *Opisthorchis*), lung flukes (*Paragonimus* spp.), and intestinal flukes (*Fasciolopsis buski*, *Heterophyes*, *Metagonimus*, *Echinostoma*, *Gastrodiscoides*, and others). The drug is remarkably safe; it is well tolerated with few, minor side effects and is suitable for mass treatment because of single dose regimen. *Resistance to PZQ*: The question has been posed whether resistance or tolerance to PZQ in schistosomes is a fact or artifact. Drug tolerance has been developed in strains selected in the laboratory. There was also evidence of drug tolerance to PZQ in a few endemic human populations; PZQ tolerant strains of *S. mansoni* proved fully susceptible to oxamniquine. To date, there is no evidence of development of clinically relevant resistance and the danger of drug resistance is considered to be lower for schistosomes than for soil-transmitted helminths [Doenhoff M et al. (2002) Trans R Soc Trop Med Hyg 96: 465]. *Oxamniquine* (a **tetrahydroquinoline**, cf. Table 2) is an alternative to PZQ for the treatment of schistosomiasis caused by *S. mansoni*. Since 1975, it has been used in a sustained control program in Brazil but in recent years Brazil has switched to using PZQ as the drug of choice. *S. haematobium* and *S. japonicum* are virtually unaffected by

therapeutic doses; it is well tolerated and there is a low incidence of mild side effects. *Metrifonate* (syn. trichlorfon, an **organophosphate**) is converted nonenzymatically at physiological pH to dichlorvos and a potent cholinesterase inhibitor; it is effective clinically only against infections with *S. haematobium*. Because of its low cost and ready acceptance metrifonate can be used as an alternative to PZQ for treatment of urinary schistosomiasis (usual dose is 7.5–10 mg/kg b. w. per os $\times 3$ at intervals of 2 weeks). Unfortunately, oxamniquine and metrifonate are no longer available commercially. **Artemisinin derivatives**, which are primarily used against malaria (cf. $\rightarrow$ Malariacidal Drugs), also exhibit antischistosomal activity. In the mid-1990s, clinical trials were carried out in China, demonstrating that artemether fully protect against *S. japonicum* infections. Chemoprophylactic treatment with artemether was started prior to contact with water containing *Schistosoma* infected snails and then continued at intervals of 2 weeks. The feasibility of this novel control strategy has been demonstrated in further clinical trials including also *S. mansoni* and *S. haematobium* in China, Egypt, the Philippines, and other countries (for more information cf. Table 2 and text below).

Trematode Infections of Animals (Economic Importance, Occurrence, Disease Patterns, Epizootiology, and Control Measures)

The life histories of all genera and species belonging to the subclass Digenea are indirect, i.e., trematodes require 1, 2 or more intermediate hosts to complete their life cycle in the definitive host; obligatory intermediate hosts are snails. The main flukes parasitic in domestic animals and humans belong to the subclass Digenea of the class Trematoda (phylum $\blacktriangleright$ *Platyhelminthes*).

LIVER FLUKES: The most common and pathogenic liver flukes in cattle, sheep, and goats are *F. hepatica* (common liver fluke), and *F. gigantica*. In humans, fascioliasis (mainly caused by *F. hepatica*) is focal in distribution and sporadic while in ruminants the infection is principally endemic and of greatest economic importance. *F. hepatica* is widespread and about

250 million sheep and 350 million cattle are at fascioliasis risk worldwide [Hillyer GV, AptW (1997) *Parasitol Today* 13: 87]. In Australia and New Zealand, up to 40 million sheep and 6 million cattle graze pastures where liver fluke is endemic. Graziers spend approximately \$10 million a year on fluke drenches alone; lost production (including liver condemnation) costs a further \$50–80 million a year (1999 estimate). Deaths account for only a part of this loss. Other significant losses in sheep include reduced production and quality of wool, reduced lambing percentages, poor growth rate of lambs, and increased costs for replacement stock. In cattle, losses include reduced production and quality of milk, lower growth rates, and lower feed conversion rates in fattening cattle (<http://www.dpi.nsw.gov.au/website/primefact446>, 2007). Thus in many countries about a quarter of the sheep and cattle population are exposed to the infection causing severe economic loss in domestic livestock. Annual losses to the world's agricultural community due to liver fluke infestation are estimated to be in excess of \$2 billion. **Pathogenesis and clinical disease:** The liver fluke can develop to sexual maturity in sheep, cattle, horses, pigs, goats, alpacas. Other hosts include kangaroos, wombats, and rabbits, which may maintain the contamination of pastures as reservoirs. During the migration phase of parasites through the abdominal cavity and liver parenchyma (causing acute/subacute fasciolosis), burrowing young flukes may produce serious, acute inflammatory tissue reactions resulting in extensive tissue damage and severe anemia (blood loss by mechanical trauma). The outcome may be "Black disease" of sheep and cattle, an acute and fatal liver disease associated with liver failure and death in 8–10 weeks. Chronic fasciolosis occurs when young flukes reach the bile ducts in the liver where they mature to adults. It is the most common form of liver fluke infection in sheep, goats, and cattle, particularly in more resistant hosts such as horses and pigs. The fluke ingests blood, which causes severe anemia and chronic inflammation and enlargement of the bile ducts. The clinical signs develop slowly (increasingly anemic, lowered appetite, pale mucous membranes of mouth and eyes, edema

under the jaw – so-called ‘bottle jaw’). Cattle have a natural resistance and under normal conditions the clinical disease is only likely in young cattle. Chronically infected cattle can spontaneously recover, and previously infected animals can partially resist reinfection. Thus cattle seem to be more resistant to fascioliasis than are sheep, possibly because of chronic fibrotic changes in the liver that form a certain mechanical barrier against reinfection. In sheep, there is no evidence of any acquired resistance to *F. hepatica* and *F. gigantica*. Acute and chronic fasciolosis can occur at any age. *Fascioloides magna*, a common trematode of deer in North America and brought in several European countries and South Africa, may cause severe disease and death in cattle, sheep, and goats by continuous tissue migration. Thus, a single migrating fluke can eventually cause the death of the host. The situation concerning *Dicrocoelium* is not clear either. In China, *D. chinensis* has been described as different from *D. dendriticum* and *D. hospes*. Young *D. dendriticum*, *D. hospes*, and *D. chinensis* (estimated prevalence of *D. chinensis* in South Korea 30–100 % in sheep, and 35 % in cattle) migrate directly from the small intestine via the common bile duct into the biliary system; they do not cause mechanical tissue damage to liver parenchyma. These small liver flukes produce *chronic tissue reactions* in the liver parenchyma as fibrosis of the Glisson’s capsule (consisting of small bile ducts, portal veins, and hepatic artery), leading to biliary cirrhosis. Heavy infections may result in loss of weight and emaciation.

Epizootiology and control measures of fasciolosis: The chronically infected sheep and cattle play an important part in contaminating pastures with million of embryonated *F. hepatica* eggs (an animal may produce one to two million eggs per day). Other domestic animals and wild animals may serve as reservoir hosts for *F. hepatica* and *F. gigantica*. Fasciolosis in ruminants (e.g., cattle, buffaloes, sheep, and goats) is found throughout the Americas, southeastern USA, Africa, Europe, and Asia (South Western Asia, and India, Central East Asia, and Southeast Asia). The disease occurs mainly in late autumn and winter. Due to the great biotic potential of *F. hepatica* and their intermediate host snails,

only a continuous and coordinated strategic application of all available measures can provide economic control of the disease. Thus control of fasciolosis should be on a preventive rather than a curative basis and should include epizootiological parameters such as fluke development in the intermediate host and weather patterns.

Preventive measures may involve (1) strategic use of flukicides to reduce the number of flukes in the host and fluke eggs on pasture; (2) intermediate host snail control (management of fluke-prone areas to reduce exposure to infection, i.e., regular clearing of vegetation from drainage channels may reduce silting and blockages that normally support snail-contaminated herbage), and (3) disease control by farm management (snail-infested pastures occupy only a small part of the animals’ grazing area; fencing off these contaminated areas is a most economic and efficient method of controlling fasciolosis; grazing management, i.e., grazing between the potentially fluke-infected areas and the fluke-free areas, or pasture rotation depending on suitable grazing properties of paddocks (e.g., more resistant cattle could be grazed on the known fluke-prone areas and are less likely to be affected and would require less treatments). Effective flukicides play an important role in the control of fasciolosis. An efficient strategic control program relying on a minimum number of treatments per year and aimed at long-term elimination of pasture contamination requires drug products that are effective against both mature and early immature flukes. More frequent treatments are necessary with drugs that are only effective against advanced mature fluke aged 12–16 weeks or older. Using anthelmintics the first of these strategies is the use of anthelmintics, based on the epidemiology of the disease. This makes it possible to determine the time of the year when the maximum effect can be achieved with the fewest possible treatments. The correct time for anthelmintic treatment depends mainly on climatic conditions and weather data. A *geographic information system* (GIS) forecast model based on moisture and thermal regime has been developed to assess the risk of *F. hepatica* infections in endemic areas [Yilma JM, Malone JB (1998) Vet

Parasitol 78: 103]. GIS can be used to complement conventional ecological monitoring and modeling techniques; it permits database management of standard maps, aerial photographs, satellite images, climate zones, and ground survey maps. Careful definition of factors affecting dynamics of fascioliasis on a geographic basis may be useful for researchers when making decisions on resource allocation and setting priorities. This makes it possible to determine the time of the year when the maximum effect can be achieved with the fewest possible treatments. Treatments are essential when clinical disease is apparent, even though it may be too late to prevent economic losses. Thus strategic treatments at epizootiological appropriate times (in late summer to avoid outbreaks of disease, and in late winter plus early spring to reduce contamination of pastures with eggs before grazing commences) are designed to minimize subsequent snail infection in the autumn and spring [Boray JC (1993) Agfact AO.9.57, NSW Agriculture, Orange, NSW: 10]. Annual programs of control for fluke may be three **triclabendazole** (TCBZ) treatments combined with other broad-spectrum anthelmintics. Using TCBZ more frequently (such as every 3 months from September) reduces fluke disease to a negligible level. However, more frequent drenching may lead to development of drug resistance. TCBZ resistance in liver fluke has been reported. The development of resistance may be delayed by alternating use of TCBZ with a closantel/oxfendazole combination or other drug combinations (cf. Table 1). Adult beef cattle (more resistant to fluke) require fewer treatments than sheep to control fasciolosis. The recommended treatments (in Australia/New Zealand) are in August/September to eliminate fluke before spring, when the conditions become favorable for fluke eggs and host snails. This is an essential treatment for all cattle (incl. young heifers and dry cows). It is advisable to treat cattle and sheep at the same time, especially if sheep and cattle are grazing on the same pasture; an additional treatment for all young cattle should be performed in April/May

to eliminate any fluke picked up during summer. Some of the available anthelmintics (cf. Table 1) are not effective against immature fluke and so are not recommended in acute fluke outbreaks. Also, they are less efficient for the strategic control of fasciolosis. The best prevention and control can be achieved with TCBZ, which affects early immature and adult fluke in particular; treatment a month before calving, and immediately after drying off will additionally improve performance in cattle.

Closantel (CST) is effective against *Haemonchus* as well as liver fluke; however, in certain areas there may be widespread resistance of *Haemonchus* against this drug. CST is effective against young mature fluke aged about 6–8 weeks, but has reduced effect on early immature fluke populations. This lower efficacy against early immature fluke is more evident where CST resistance in immature *F. hepatica* has emerged. The closantel/oxfendazole combination has good synergistic efficacy against susceptible fluke aged 4 weeks and can be successfully used against TCBZ-resistant fluke. CST, or the above combination (both approved for use in sheep in Australia and elsewhere), may be suitable for the late winter/early spring treatment. Successful prevention and control of the disease have been achieved with *diamfenetide* (~100 % efficacy against 1-day-old to 9-week-old flukes, cf. Table 1) and *rafoxanide* (efficacy ~86–100 % against 6-week-old stages to adult flukes, cf. Table 1); however, these drugs are no longer available commercially in various countries. **Albendazole**, **clorsulon** and **bromsalans** affecting only adult stages of *F. hepatica* do not play a role in strategic control programs. This is also true for older drugs such as *bithionol*, *hexachlorophene*, *bromofenofos*, and *niclofolan* (not considered in Table 1), which may still be used in some countries and are no longer approved as flukicides in Australia, USA, EC, and elsewhere. Only at doses approaching toxic levels, these drugs affect immature flukes aged 8–10 weeks. Also, drug combinations such as *oxyclozanide*/*levamisole*, and **clorsulon**/**ivermectin** (approved

for use in lactating cows, cf. Table 1) are used against adult fluke aged 12–14 weeks or older including gastrointestinal nematodes and lung-worms; if the property is heavily contaminated, treatment in lactating cows should be performed monthly during summer and autumn.

Vaccines may offer a more effective and acceptable alternative to drugs because they are regarded as safe, environmentally friendly, and leave no chemical residues in the food chain. Until now, there is no commercially available vaccine against liver fluke. The main market opportunity for a vaccine (~US\$ 182 million) is in those countries with intensive cattle and sheep farming industries (Australia, Argentina, Brazil, Europe, New Zealand, and the USA). A novel recombinant protease (University College Dublin Ireland owns Intellectual Property) has demonstrated effective protection against liver fluke in cattle and sheep. Current work is focused on developing a formulation and administration regime, which will induce maximal protection using the most commercially viable adjuvant. Another available strategy for controlling liver fluke infection in livestock is *intermediate host snail control*. The snails (e.g., *Lymnaea* spp.) produce eggs throughout the year and there is a marked increase in reproduction from spring to late autumn. Each snail may produce 3,000 eggs a month and one generation of snails from egg to egg takes only about 1 month under optimum conditions. *Lymnaea* survives in dry mud for at least 1 year, moves with and against the water current for long distances, and tolerates low temperatures. Metacercariae encysted on grass blades; in the presence of sufficient moisture they will remain alive for many weeks, depending on the temperature (survive longer at below 20 °C, higher temperatures and desiccation will destroy them in a short time). Fluke survive for many years in the liver of infected sheep; the adult fluke produces between 20,000 and 50,000 eggs a day, and over a long period. In cattle, the egg production declines as the animal develops a natural resistance to chronic infections. The

epizootiology of the disease is influenced by the grazing habits of animals. Cattle often graze in the wet marshy areas favored by the fluke snail, so the eggs are deposited in a suitable environment. If food is available elsewhere, sheep and goats prefer to graze away from marshy pastures. Long wet seasons are usually associated with a higher infection rate but sheep are more likely to ingest large numbers of cysts during dry periods after a wet season, when the animals are forced to graze in swampy areas, resulting in heavy infection. It is unlikely that *chemical control* or *biological means* (living antagonists or predators of snails like ducks and frogs ingesting snails in endemic areas) will eradicate the snail population, because it reproduces readily. Rapid repopulation from adjoining areas can occur. Chemical control by the use of highly active and for the environment toxic molluscicides (e.g., niclosamide ethanolamine salt, former Bayluscid, N-tritylmorpholine, former Frescon, and sodium pentachlorophenate or copper sulfate) is now obsolete. These agents not only kill snails but also other invertebrates and fish. Therefore, the use of molluscicides has been severely restricted in most countries (no registered products for snail control in the USA, Australia, EC, and elsewhere). Current strategic control of fluke infections in cattle and sheep relies on drug treatment and farm management (†) including improved drainage and regular clearing of vegetation from drainage channels. In low-lying areas, adequate drainage would prevent accumulation of water (snails multiply for extended periods in wet, low-lying areas). Draining marshy pastures and building dams may reduce snail habitats and increase grazing areas.

There are no efficient control measures for preventing *Dicrocoelium* infections in sheep and cattle. Intermediate hosts (snails, ants) of *Dicrocoelium* spp. are known to be widespread in arid areas and have high reproductive rates. However, intermediate host snail/ant control is impracticable though ant populations might be reduced by destroying nests in certain districts.

But Formicinae are protected animals and control of ants is basically prohibited. Further, none of the antitrematodal drugs available is effective enough to remove all adult *Dicrocoelium* and obtain permanent improvement of liver function and regeneration of liver parenchyma. Nevertheless, common strategic drug treatments in early spring, summer, and autumn may help to reduce production loss in sheep and cattle. *Benzimidazoles* show some activity against *Dicrocoelium* infection at relatively high (not approved and uneconomic) dosages given orally (e.g., albendazole: 7.5–15 mg/kg $\times$ 2: weekly interval; fenbendazole: 20 mg/kg for 5 days; febantel: 50 mg/kg for 2 days).

INTESTINAL FLUKES: Global infections due to amphistomes (e.g., family Paramphistomatidae) in cattle and sheep are of minor economic (veterinary) importance. Thus, the pathogenicity of these flukes is lower than that caused by the hepatic trematodes and intestinal nematodes. There are three groups of amphistomes living in gastrointestinal tract of animals: (1) *Paramphistomum* spp. (13 species, and several other genera) inhabiting the duodenum as larvae and invading the rumen at a later developmental stage (major pathogenic effect caused by juvenile stages in duodenum); (2) *Gigantocotyle* spp. and *Eurytrema* (belonging to Dicrocoeliidae) inhabiting the duodenum and bile ducts; and (3) *Gastrodiscus*, and *Homalogaster* living in the lower alimentary tract (considered to be of minor importance). Young paramphistomes are deeply embedded into the mucosa of the small intestine causing mechanical damage of the epithelial cells by their large posterior (ventral) sucker. Adult *Paramphistomum* living in the forestomachs of ruminants may produce only slight clinical signs. During the migration phase in the duodenal wall and abomasum wall the young rumen flukes are highly pathogenic to young, naive (previously uninfected) sheep and cattle, and large numbers of larval stages can cause clinical signs, such as loss of appetite (anorexia), diarrhea (dehydration),

anemia (loss of protein), retarded growth, and even mortality. As a rule, susceptible calves, and lambs should not be grazed together with adult animals, as these are chronically infected in most cases. If an outbreak of disease occurs all animals should be treated and removed immediately from pasture. *Gigantocotyle explanatum* (a common paramphistome in cattle in India) may cause pathological damage similar to those caused by *F. hepatica* or *F. gigantica*. There are many other genera and species of intestinal trematodes in ruminants, equines (e.g., *Gastrodiscus aegyptiacus*), and pigs (e.g., *Fasciolopsis buski* and *Gastrodiscus aegyptiacus*). In dogs, there are also a large number of intestinal flukes, such as heterophyids, echinostomes, and diplostomes, which show little host specificity and can also infect humans (cf. Table 2). Adult stages of these genera are nearly without pathological findings and, in general, do not cause clinical disease. Intestinal flukes also frequently occur in birds and rodents, which may form reservoirs for infections in humans and livestock. Because there is little host specificity intestinal trematodes are often found in unusual hosts. *Farm management techniques and control measures* in the treatment of rumen fluke infections (paramphistomiasis) in cattle, sheep, and goats are similar to those used in integrated control for fascioliasis. Paramphistomes respond to flukicides used for the control of fascioliasis in ruminants; some anticestodal agents (► [Cestodocidal Drugs](#)) such as bithionol, resorantel, and niclosamide affect them too. However, compounds may exhibit different chemotherapeutic activities in cattle or sheep, or their actions on juvenile flukes in the intestinal and abomasal walls, and adult flukes in the rumen may differ as well. For instance, *bithionol* exhibits better efficacy against juvenile than adult flukes whereas *oxyclozanide* or resorantel are effective against both immature and mature stages.

BLOOD FLUKES: The worms live in the vascular system of vertebrates. Distribution patterns of human and animal blood fluke infections

(*Schistosoma* spp. causing schistosomiasis in humans cf. Table 2) are mainly restricted to the tropical and subtropical areas. Two genera of animal schistosomes of importance belong to the genera *Schistosoma* and *Orientobilharzia*. Within *Schistosoma* there are species of zoonotic importance, which infect also man, such as *S. japonicum* (described from cattle, buffaloes, goats, and pigs), *S. mattheei* (found in cattle and buffaloes) and *S. curassoni* (found in cattle, goats, and sheep). The nonzoonotic species also have limited host specificity and include *S. bovis* (cattle, sheep, and goats), *S. indicum* (cattle, goats, and sheep), *S. spindale* (cattle and goats), *S. nasalis* (cattle, buffaloes, and goats) and *S. incognitum* (pigs). *Orientobilharzia turkestanicum* was described as occurring in cattle and sheep. Schistosomiasis in ruminants is known to occur often focally in endemic areas because of aggregated distribution of the intermediate snail hosts and the restricted stock movement from one farm to another. Thus individuals from the same herd are likely to be exposed to similar ranges of cercarial challenge. The per-oral route of infection may be of importance in cattle, particularly when animals drink infrequently and swallow large volumes of water. In China, *S. japonicum* infections are known to be an important zoonosis; millions of cattle may be infected and develop a natural acquired immunity to this schistosome infection. Generally the pathogenicity of blood fluke infections in grazing animals is considered to be low, only occasionally causing serious problems (particularly in cattle) in Africa, the Middle East, and Asia, e.g., India and China (for further information on geographical distribution and prevalence of common trematode infections cf. FAO Corporate Document Repository <http://www.fao.org/DOCREP/>). In most parts of endemic regions chemotherapy (e.g., with PZQ = praziquantel) appears not to be a suitable mean for controlling schistosomiasis in domestic livestock (cf. current status of flukicides: PZQ ↑) though it is the current method of choice in the control of human schistosomiasis (Table 2).

Trematode Infections of Humans (Prevalence, Disease Patterns, and Control Measures)

BLOOD FLUKES (SCHISTOSOMIASIS): *Clinical manifestations, pathogenesis, and pathology:*

Exposure to infection can begin shortly after birth and maximum risk of exposure may occur in children aged 10–14 years. The lower prevalence in adults possibly is due to partial immunity and decreased exposure to water containing cercariae. Symptoms of the disease correlate with developmental stages of the blood flukes: (1) Cercariae emerged from aquatic snails penetrate the skin and produce an allergic dermatitis (pruritic papular rash) at site of entry; nonhuman avian schistosomes cause similar symptoms. (2) The tailless cercariae (schistosomula) migrate into the lungs via the venous circulation. From there schistosomula are carried through the left heart into the systemic circulation, finally reaching the portal system (in case of *Schistosoma mansoni*, *S. japonicum* infections) or the umbilical plexus (*S. haematobium*). Cardiopulmonary schistosomiasis is associated with larval pneumonitis causing cough, mild wheezing, low-grade fever, and eosinophilia. (3) Adult worms rarely are pathogenic. In the venous blood, male and female worms mate, and the female lays eggs. Prepatent period, (time between penetration by cercariae and first appearance of eggs in feces or *urine) is ~35 days for *S. mansoni*, *S. japonicum* (others) and ~70 days for **S. haematobium*, respectively. The female worm may live for approximately 3–8 years and lays eggs throughout her life span. In heavy infection, symptoms are similar to those seen with schistosomula (cough, fever, and eosinophilia).

Acute manifestations: Clinical symptoms reflect host responses to toxic or antigenic substances derived from the parasites and eggs. Eggs cause so-called Katayama fever (termed after the District in Hiroshima Prefecture) and schistosomiasis. High fever, lethargy, and myalgia (less common are cough, headache, anorexia, and rash) may suddenly start after termination of prepatent period and is observed most commonly

with *S. japonicum* but also has been reported with *S. mansoni*. These symptoms can mimic any acute viral, bacterial, or malarial illness. An anamnesis that includes freshwater exposure in an endemic area may confirm an infection with schistosomes. Katayama syndrome may be due to host's response against egg antigens released in serum and forming immune complexes. It is obviously not associated with granulomatous inflammation around schistosome eggs; *Granuloma formation* (aggregations of mononuclear phagocytes, neutrophils, particular eosinophils, lymphocytes, plasma cells, fibroblasts, and giant cells) has been considered to be the result of delayed-type hypersensitivity reactions mediated through T helper cells (Th1 and Th2 cells, phenotype CD4+) mediated immune response to soluble egg antigens. Thus, schistosomiasis is principally due to immunological reactions of the host to *Schistosoma* eggs trapped in tissues that results in clinical disease. Symptoms and signs depend on the number and location of eggs trapped in the tissues. Initially, the inflammatory reaction is readily reversible. In the latter stages of the disease, the pathology is associated with collagen deposition and fibrosis, resulting in organ damage that may be only partially reversible.

Chronic manifestations: Most patients are asymptomatic or mildly symptomatic. Only a small proportion of the endemic population harbors a heavy worm burden that later leads to clinical complications. Typically, onset may be insidious and depends on the species of schistosome, the duration, and severity of infestation. The immune response to eggs of *S. mansoni*, *S. mekongi*, *S. intercalatum*, and *S. japonicum* causes intestinal tract and liver disease (abdominal pain, diarrhea, dysentery, dyspepsia, flatulence, pain in the left hypochondrium due to the enlargement of the spleen). In the later stages of hepatic schistosomiasis, abdominal distention, lower limb edema, hematemesis, and melena (dark stools containing blood) can occur. The most common complication of gastrointestinal schistosomiasis is periportal fibrosis leading to

portal hypertension and gastrointestinal hemorrhage and then to hepatosplenomegaly, pedal edema, pallor, distended abdominal veins, and ascites. Symptoms of liver failure are rare unless other infectious, toxic, or malignant causes of hepatitis are present leading via chronic hepatitis to cirrhosis. Thus, people coinfecting with either hepatitis B or C and *S. mansoni* have been shown to have rapid progression of liver disease. An important complication occurring in about 5 % of patients with hepato-splenic *S. mansoni* is schistosomal cor pulmonale and anemia (palpitations, generalized pain, easy fatigability, weakness, and dyspnea on exertion, hemoptysis = spitting of blood-stained sputum). *S. japonicum* may cause cerebral schistosomiasis in 2–4 % of patients (seizures; headache; and myelo-radiculopathy with lower limb and back pain, bladder dysfunction, paresthesia, and lower limb weakness); in a few cases CNS involvement may also occur with other species. Spinal disease usually presents as transverse myelitis and primarily is due to *S. mansoni* infection. *S. haematobium* causes urinary tract disease (dysuria, urinary frequency, and terminal hematuria) and only rarely intestinal or liver disease. There may be renal failure due to obstructive uropathy, pyelonephritis, or bladder carcinoma (latter may occur 10–20 years after initial infection); immune complexes and worm antigens may deposit in the glomeruli causing glomerulonephritis and amyloidosis. Female genital schistosomiasis (FGS) is characterized by lesions in the lower genital tract (cervix, vagina); the history includes postcoital bleeding, genital ulceration, irregular menstruation, and pelvic pain. FGS has been identified as a major social and medical problem that may facilitate the spread of some sexually transmitted diseases such as HIV and human papilloma virus (HPV).

Burden of schistosomiasis: Morbidity caused by schistosomiasis and *soil-transmitted helminth infections* (cf. ► [Nematocidal Drugs](#), [Man](#)) remain major public health concerns in many tropical and subtropical regions of the world,

particularly in the poorest developing countries; cost-effective solutions are both available and deliverable. Recent World Health Organization (WHO) reports estimate that 500–600 million people in 74 tropical and subtropical countries are at risk for schistosomiasis. Gastrointestinal disease due to *S. mansoni* occurs in 52 countries, including Caribbean countries (Saint Lucia, Antigua, Montserrat, Martinique, Guadeloupe, Dominican Republic, Puerto Rico), eastern Mediterranean countries, South American countries (Brazil, Venezuela, Surinam), and most countries in Africa. Urinary tract disease produced by *S. haematobium* affects 54 countries in Africa and the eastern Mediterranean. Other *Schistosoma* spp. that can cause gastrointestinal diseases include *S. intercalatum*, *S. mekongi*, and *S. japonicum*; latter species is endemic in the western Pacific region (e.g., Philippines, China, Indonesia, and Thailand), *S. mekongi* infection occurs in the Mekong River area of Southeast Asia (Cambodia, Laos, and Thailand) and *S. intercalatum* is found in several countries within the rain forests of central Africa. Over 200 million people in these countries are infected with schistosomes and of these about 10 % having a severe clinical disease. Persons at risk include those who live or travel in areas where schistosomiasis occurs and who come into contact with fresh water where the appropriate type of snail intermediate host is present.

Control measures and drug treatment programs: According to the WHO, the global distribution of schistosomiasis has changed in recent years. It has been eradicated from Japan and the Lesser Antilles islands; transmission has been stopped in Tunisia and is very low in Morocco, Saudi Arabia, Venezuela, and Puerto Rico. The morbidity caused by disease has been controlled in Egypt, China, and the Philippines mainly by widespread use of *praziquantel* (PZQ) and *oxamniquine* and PZQ in Brazil. In 2001, the WHO has developed a strategy aimed at control of morbidity due to schistosomiasis and intestinal worms in sub-Saharan Africa [World Health

Organ Tech Rep. Ser (2002) 912: i–vi, 1–57]. The goal of World Health Assembly resolution is to attain a minimum target of regular administration of chemotherapy to >75 % of all school-age children at risk of morbidity by 2010. Thus, school-age children should be treated on a regular basis during their childhood, thereby improving their health and nutritional status and protecting them from liver fibrosis and bladder complications, which would otherwise occur later in life. PZQ treatment should be also offered to pregnant women (benefits of treatment greatly outweighing theoretical drug toxicity) and to adults infected or at risk of developing morbidity by the disease. Similarities in the population at risk and in the tools required to combat the problems have prompted moves toward a combined approach to the control of schistosomiasis (and soil-transmitted helminthiasis caused by nematodes). Such an approach relies largely on epidemiological surveillance, health education (in endemic areas, people should avoid contact with fresh water; need for providing a safe water supply, the role of snails as intermediate host for blood flukes), improvements in hygiene and sanitation (improving water sanitation and avoiding schistosome-contaminated urine or stool), and in the first place, regular treatment of high-risk groups, particularly school-age children. The cost of recommended anthelmintic drugs has now fallen to a level at which it should no longer deter Member States from making treatment widely available in endemic areas. Thus PZQ and oxamniquine (no longer commercially available in the USA) are used commonly, but PZQ is the treatment of choice for all species of schistosomiasis (dose regimen, cf. Table 2). Clinical studies demonstrated that *artemether* (derivative of dihydroartemisinin) which is used as antimalarial drug, is also active against all three major schistosome parasites (mainly schistosomula). In addition, clinical studies have shown that artemether is a suitable prophylactic agent if given once every 2–4 weeks; also trials that included a combination of artemether and

praziquantel demonstrated beneficial effects (for more information on current status of control programs, PZQ delivery strategies, price of PZQ, and alternative drugs cf. Table 2). To date, no prophylactic acting or vaccine is available. However, clinical trials involving human volunteers are underway to develop an effective vaccine against schistosomiasis.

LIVER FLUKES: Human infections with the cosmopolitan liver flukes *Fasciola hepatica* and *Dicrocoelium dendriticum* may occur by chance in endemic areas depending on eating habits of people (cf. Table 2). When a person eats contaminated plants (e.g., by eating watercress from naturally contaminated creeks), the metacercariae leave their cysts, pass through the wall of the intestine, and enter the liver, where they cause inflammation and destroy tissue. Following prepatent period (10–15 weeks), the adult flukes move to the bile ducts and produce eggs. *Acute fascioliasis* is characterized by abdominal pain with headache, loss of appetite, anemia, and vomiting. Some patients may develop hives, muscle pains, and jaundice (yellow-color to the skin and whites of the eyes). *Chronic forms* of the disease may produce complications, including blockage of the bile ducts or the migration of adult flukes to other sites of the body. Drug of choice for treating fasciolosis is *triclabendazole* (a benzimidazole), an alternative may be bithionol (cf. Table 2); PZQ proved ineffective against *Fasciola* (for reason cf. Current status of flukicides†). Human infections with *Opisthorchis* spp. and *Clonorchis* are widespread, affecting about 30 million people in China, Korea, Japan, Southeast Asia, and India. The life cycle of these liver flukes is similar to that of *F. hepatica* except that the metacercariae are found under the scales of freshwater fish rather than on plants. Dogs, cats, and other mammals that eat raw fish may serve as reservoir hosts. Man becomes infected by consumption of raw or improperly cooked cyprinoid fish chiefly coming from contaminated aquacultures. The symptoms of the diseases resemble those of fascioliasis and include both acute and

chronic forms. The acute syndrome may be difficult to diagnose (absence of typical eggs in feces during prepatent period); patients with the chronic form of the disease may show low-grade fever, diarrhea, inappetence, fatigue, and an enlarged liver that feels sore when the abdomen is pressed. Safe and effective oral drugs are available for the treatment of both opisthorchiasis and clonorchiasis. PZQ is the drug of choice for treating all species of *Opisthorchis* and *Clonorchis sinensis* (cf. Table 2). Effective snail control in order to interrupt transmission of cercariae to fish is impracticable; it is also unlikely that chemical control (use of toxic molluscicides is obsolete and prohibited in most countries) or biological means will eradicate the snail population, because of its rapid repopulation from adjoining areas. Ammonium sulfate added to egg-contaminated feces may kill the eggs and so interrupt life cycle of parasites in freshwater snails.

Carcinogenic risks due to liver and blood flukes: In 1994 the International Agency for Research on Cancer (IARC) decided to include in its monograph series on carcinogenic risks to man, schistosomes and liver flukes [International Agency for Research on Cancer (Lyon 1994) schistosomes, liver flukes and *Helicobacter pylori*. IARC Monographs on the evaluation of carcinogenic risks to humans, 61: 121–175]. The evidence here comes from epidemiological studies (helpful animal cancer model are not available). *Opisthorchis viverrini* and *S. haematobium* are classified as carcinogenic (category 1, main cancer cholangiocarcinoma and bladder cancer, respectively). *Clonorchis sinensis* and *S. japonicum* are classified as probably or possibly carcinogenic (category 2A/2B, main cancers cholangiocarcinoma and gastrointestinal cancer, respectively). *O. felinus* and *S. mansoni* are nonclassifiable because of insufficient human evidence (category 3).

LUNG FLUKE INFECTION: *Paragonimus westermani* and some other 16 species of the *Paragonimus* genus cause paragonimiasis in

man (~21 million infected people worldwide). Infections are often due to cultural-specific habits of minorities in certain areas of Southeast Asia, West Africa, and the Americas. Numerous reservoir hosts (various crustacean-eating wild carnivores and omnivores) makes control of *Paragonimus* nearly impossible; boiling the freshwater crabs or crayfish (second intermediate host; all organs of the crab/crayfish can harbor metacercariae) for several minutes until the meat has turned opaque will kill metacercariae. Slight infection may be asymptomatic in humans. The disease is insidious (first nonspecific cough that becomes chronic and produces blood-tinged sputum followed by pleural pain and dyspnea). Primary manifestation can be complicated by recurrent pneumonitis, lung abscess, and pleural effusion. Lesions in brain can lead to seizures and resemble those seen in cysticercosis (cf. ► [Cestodocidal Drugs](#)). Chronically infected patients may show clubbing of fingers and toes. PZQ is the drug of choice for the treatment and control of *Paragonimus* infections (dose regimen cf. Table 2).

INTESTINAL FLUKES: They are widely distributed throughout the Far East and Southeast Asia, the Indian subcontinent, West Africa, and Mediterranean countries (*Heterophyes heterophyes* can be found especially in the Nile delta region of Egypt). Although intestinal flukes are of minor medical importance they may cause morbidity, which is only observed in patients with heavy worm burdens who suffering from severe cachexia and prostration. There are numerous species living attached to the epithelium of the small and large intestine. *Fasciolopsis buski* (giant intestinal fluke, ~15–20 million infected people) occurring in areas of the Far East is transmitted by metacercariae attached to various aquatic plants (water chestnut, lotus on the roots, water bamboo, and other aquatic vegetation). Young flukes attach to the duodenal and jejunal mucosa and become mature in approximately 3 months. In severe infections, they may attach also to the ileum or colon. The adult worm

produces traumatic, toxic, and obstructive damage to the intestinal mucosa. At the site of attachment, deep inflammatory ulcerations may be seen. Large numbers of this fluke provoke excess mucous discharge and can obstruct the lumen. Metabolites released from adult stages in the lumen and then absorbed may cause intoxication and sensitization. Malabsorption can lead to hypoalbuminemia, protein-losing enteropathy, and impaired vitamin B₁₂ absorption. *Echinostoma ilocanum* (12 species) is the most common species of this genus occurring in man; metacercariae are transmitted by eating raw or undercooked freshwater mollusks (snails or clams). Adult worms attach to the mucosa of small intestine and produce inflammation, superficial ulcers, and local necrosis of the mucosa. Small numbers of this fluke are asymptomatic but large ones produce diarrhea, flatulence, and intestinal colic. *H. heterophyes* (ten species, ~10 million infected people, uncommon but widely distributed) and *Metagonimus yokogawai* (most common heterophyid fluke in areas of the Far East and Mediterranean basin) encyst under the scales or in the skin of various fish species. Following ingestion of infected raw or undercooked fish, the small flukes (closely related species measuring 1–2.5 mm in length and 0.4–0.75 mm in width) attach to and also invade the mucosa of the jejunum and ileum thereby causing inflammation, shallow ulcers, and superficial necrosis of the mucosa. Symptoms include vague abdominal complaints, dyspepsia, mucous diarrhea, and intestinal colic. Flukes eventually become encapsulated, or they form sometimes clots (emboli) together with their eggs entering blood vessels and may lodge in the brain producing symptoms similar to cerebral hemorrhage, or worm/egg clots enter the mesenteric lymphatics and travel to the heart causing myocarditis and chronic congestive heart failure; death may occasionally occur by an embolic infarct if clots obstruct important arteries in the brain or heart. Other intestinal flukes that rarely cause intestinal infection in man are *Gastrodiscoides hominis* occurring in India,

Southeast Asia, and parts of the former USSR (transmitted by eating uncooked aquatic plants; adult worms attach to wall of colon and cecum), *Nanophyetus salmincola* occurring in eastern Siberia and Northwestern USA (transmitted by eating raw infected fish, adults attach to small and/or large intestine), or lecithodendriids (occurring in a wide variety of insectivores vertebrates, e.g., bats) such as *Phaneropsolus bonnei* and *Prosthodendrium molenkampii*, minute flukes that may infect people in Southeast Asia (Thailand and Indonesia) presumably by feeding upon infected larval or adult insects in regions where these are local delicacies, or by accidentally ingesting insect larvae with aquatic vegetables or water. PZQ is the drug of choice for the treatment and control of all intestinal fluke infections (dose regimens, Table 2).

Tremazol®

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Compound to treat fish infected by ► [trematodes](#) and ► [cestodes](#). The product contains 74.7 mg praziquantel per ml. Trematodes on the surface and gills as well as tapeworms inside the body are killed.

Contents: 1 ml of the product is diluted in 15 l water of an aquarium.

Use: Incubation for about 6 h then change of 80 % of the water.

Producer: Fa. Alpha-Biocare GmbH, Düsseldorf, Germany (www.alphabiocare.de).

Seller: Fa. Sera, Heinsberg, Germany (www.sear.de).

Trench Fever

Disease with 3–8 repeated fever phases (all 5 days = therefore also called 5-days fever) due to infection with *Bartonella quintana*-bacteria. These bacteria being previously members of the genus ► [Rochalimea](#) are transmitted by ► [lice](#).

Therapy

Tetracyclines.

Trepomonas

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This genus belonging to the ► [Diplomonadida](#) includes several species, which parasitize in fish reaching a size of about $12 \times 7 \mu\text{m}$. Treatment in aquarium fish can be done by Flagello® produced by Fa. Sera (Heinsberg, Germany).

Triactinomyxon ignotum

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Stage of ► [Myxosoma cerebralis](#). Formerly, the phase within the tubificid worms was described as

Triactinomyxon ignotum, Fig. 1 Diagrammatic representation of the life cycle of *Myxosoma* (syn. *Myxobolus*) *cerebralis*. 1–3 After trouts have ingested an infected tubificid worm, the *Triactinomyxon* stages release uninuclear cells (sporoplasms), the nuclei of which become divided. 4–9 Via further nuclear and cytoplasmic divisions finally many spores are formed in the cartilage (9), which are set

free when the trouts die. 10–16 If aquatic annelid worms (Family Tubificidae) ingest such spores, the sporoplasm hatches and starts divisions, which finally leads to the production of the so-called *Triactinomyxon* stages, which possess polar capsules and many included sporoplasms (16). CY cytomere, N nucleus, P pericyte, PF polar filament, PK polar capsule, S sporogonic cell, SP sporoplasm

***Triactinomyxon ignotum*, Fig. 2** Light microscopic and diagrammatic representation of a typical binucleated spore of *Myxosoma cerebralis*. *N* nucleus, *PK* polar capsule, *S* wall of the spore, *SP* sporoplasma with two nuclei

own species. Now it is clear that these stages belong to the long known life cycle of *Myxosoma* (syn. *Myxobolus*) *cerebralis* parasitizing trouts and related fish (Fig. 1). The infection leads to malformations of the fish host and often to death. Triazines can be used to treat infected pond and aquarium fish as was shown by Mehlhorn (Fig. 2).

Triatoma Infestans

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

***Triatoma Infestans*, Fig. 1** Light micrograph of an adult *T. infestans* raptor bug, which may transmit the agents of

Tribocytic Organ

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This organ is characteristic for strigeid digenean trematodes (see ► [Digenea](#), holostomes). It was interpreted as third sucker-like organ, since it is somewhat protrudable and located in the ventral median line of these trematodes. However, transmission electron micrographs showed that the tegument is densely covered there by numerous microvilli, which support a better attachment at the host's intestinal wall. Furthermore the cells below the tegument and the muscle layer are densely filled with huge numbers of different granules (ranging 0.1–0.2 µm in diameter) and by lipid droplets. Thus the recent interpretation postulates that this peculiar protrudable region of the tegument (called tribocytic organ), which appears in light microscopy as circumscribed region below the ventral sucker, excretes substances, which help to destroy the intestinal microvilli and cells of their host. This makes it easy to take up the host cell cytoplasm via pinocytosis and probably also to enhance the attachment at the intestinal wall.

Trichinella spiralis

Name

Greek: *thrix*, *trichos* = fine hair, *ella* = small;
Latin: *spiralis* = enrolled.

Classification

Species of ► [Nematodes](#).

General Information

Originally it was claimed that there is only one worldwide occurring species (► [T. spiralis](#)).

Trichinella spiralis, Fig. 1 Life cycle of *Trichinella spiralis*. 1–2 The adults (male 1.5 mm × 40 µm, female 3–4 mm × 60 µm) live for 6 weeks (at the maximum) in the small intestines (being anchored in the mucous layer) of many carnivorous and omnivorous animals including man. Beginning from the 5th day after infection the females

release (over a period of 4–16 weeks) in total about 2000 larvae (► [viviparous](#)) which hatch from their eggshells while still inside the single uterus (UT). The hatched larvae (LA) measure about 100 × 8 µm and are characterized by rounded poles and an extremely long esophagus (ES); they eventually enter the wall of the intestine and are carried

However, up to now 13 genotypes have been described, which were considered to belong to eight defined species. The size of the adults is tiny (males, 1–1.8 mm; females, 1.4–3.7 mm), their oesophagus is lined with the typical stichocyte-cells. The males have small leaflike appendices for copulation, but do not possess spicula. Based on alloenzymes and DNA-analysis the following species were described:

1. **Worldwide:** *Trichinella spiralis* (life cycle synanthropic in pig, rat, horse, camel, dog, fox, bear, **humans**; muscle cysts with capsule),
2. **Arctic:** *T. nativa* (cycle sylvatic; muscle cyst with capsule; highly resistant to freezing),
3. **Moderate climates:** *T. britovi* (cycle sylvatic, muscle cysts with capsule),
4. **Africa:** *T. nelsoni* (cycle sylvatic, muscle cyst with capsule),
5. **USA, Asia:** *T. pseudospiralis* (cycle sylvatic, muscle cyst without capsule),
6. **Europe, North America:** *T. murreli* (cycle sylvatic, muscle cyst with capsule),
7. **Papua-New Guinea:** *T. papuae* (cycle sylvatic, muscle cyst without capsule),
8. **Zimbabwe:** *T. zimbabwensis* (in crocodiles, without capsule).

Trichinella spiralis, Fig. 2 LM of an adult female and a couple (arrow)

Trichinella spiralis, Fig. 1 (continued) away by the hepatic portal system through the liver, heart and lung, and thus are distributed by the arterial system throughout the body of the same host (which thus is the final and intermediate host). 4 When larvae reach skeletal muscles, they penetrate individual fibers and begin to grow, reaching up to 1 mm in length (without molt); up to seven larvae have been seen within a single fiber which is altered due to the parasitism. At first, the region around the worm becomes amorphous (due to disappearance of sarcomeres) and finally a broad dense outer, but still intracellular, zone is produced, apparently by deposition of primarily metabolic material (AC) leading to some sort of a capsule. Outside this capsule thickening may be brought about by infiltration of leukocytes and calcification

(beginning about 10 months after infection). Such encysted worms are infectious for many years; transmission occurs again when such larvae are ingested by another omni- or carnivorous host. In the intestine excystation proceeds; however, the number and location of the following molts are still a matter of controversy. AC anlage of a capsule (at the inner periphery of an infected muscle fiber), AN anus, CL ► cloaca, CO copulatory appendages, DE development of fertilized eggs, DI disintegrated ► cytoplasm of the host muscle fiber, EM esophagus (muscular region), ES esophagus (stichosomal region), HN host cell nucleus (unchanged), HY hypertrophied host cell nucleus, IN intestine, LA larvae, M mouth, MF muscle fiber (uninfected), MT muscle trichine, NR neural ring, OV ovary with eggs, TE ► testis, UT uterus, VU vulva

Trichinella spiralis and Related Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *trichos* = tiny hair; *spira* = winding.
Latin: *spiralis* = wound.

Geographic Distribution/Epidemiology

The different species of the genus *Trichinella* are worldwide distributed (Table 1) but occur in

Trichinella spiralis and Related Species, Table 1 *Trichinella* species

Species	Main hosts	Distribution
<i>T. spiralis</i> (with capsules)	Pigs, rats, bears, dogs, cats, humans, and also horses (if they ingest larvae containing meat-eating beetles)	Worldwide
<i>T. britovi</i> (with capsules)	Foxes, wolves, wild cats, bears, rodents, pigs, humans, and horses	Europe, North Africa, Arabian Half-Island
<i>T. murrelli</i> (with capsules)	Racoons, foxes, coyotes, bears, dogs, humans, and horses	North America
<i>T. nativa</i> (with capsules)	Ice bear, brown bear, tiger, wolves, pigs, dogs, cats, humans, and seals	North America, Eurasia, Europe
<i>T. nelsoni</i> (with capsules)	Lions, leopards, cheetas, wild pigs, and humans	Africa: South of the Sahara
<i>T. papuae</i> (without capsules)	Wild pigs, pigs, crocodiles, and reptiles	Papua New Guinea
<i>T. patagonensis</i>	Jaguar, cats	Southern South America
<i>T. pseudospiralis</i> (without capsules)	Rodents, foxes, pigs, raptor birds, kangaroos, and humans	Focally in USA, Europe, Asia, Australia
<i>T. zimbabwensis</i> (without capsules)	Crocodiles, pigs, rats, monkeys, and reptiles	Africa: Zimbabwe, Mozambique

special countries in different rates. In countries without meat control, in slaughter houses infection rates are still high as they had been in Europe in the years 1850–1900, when human death cases due to trichinellosis had been common (Fig. 1).

Morphology/Life Cycle

The adult worms (Fig. 2) belong to the worm phylum ► **nematodes**. Males and females are very small: females reach a size of 3 × 4 mm × 60–100 µm, males are only 1.4–1.6 mm long. Both obtain maturity inside the intestine of carnivores and omnivores (inclusive humans). Life span of adults is rather short and does only rarely exceed 2 months. After copulation (Fig. 2) females give birth to a total of about 2,000 larva, each of which measures about 90–120 µm in length and are characterized by a rounded anterior and posterior pole (Fig. 3). These larvae penetrate into the intestinal wall and become transported by blood and lymph into the muscles of their hosts, where they enter muscle fibers, which are not destroyed by the penetration process (Figs. 1, 3, 4, 5, and 6). The larvae reach

infectivity for other carnivores or omnivores already within 3 weeks, but they are also able to survive inside their host cell for up to 20 years (in humans). During this period the larvae (up to six were seen in a single muscle fiber; Figs. 3, 4, 5, and 6) stimulate the host cell to dedifferentiate itself and produce a cytoplasmic layer around the larva (Fig. 4). In the same time the host cell nuclei grow up and reach an enormous size. In some hosts such infected cells become surrounded by degenerating host cells, which together with Ca²⁺ inclusions form a special cyst wall. This process of capsule formation may start about a half year after the infection. However, the thus enclosed larva remains infectious for years. Capsule formation does not occur in all species (see Table 1). If humans or other potential hosts ingest raw, larvae-containing meat the worms become mature within a short time of about 7–14 days and start production of larvae (Fig. 2, and 3).

In former times, when species descriptions were mainly based on morphological criteria, it was believed that only one species of the genus *Trichinella* existed and was named *T. spiralis*. Additional use of molecular biological criteria led to the establishment of eight different species,

***Trichinella spiralis* and Related Species, Fig. 1** Diagrammatic representation of the life cycle of *Trichinella spiralis*. 1–2 The adults (male 1.5 mm × 40 μm, female 3–4 mm × 60 μm) live for 6 weeks (at the maximum) in the small intestines (being anchored in the mucous layer) of many carnivorous and omnivorous animals including man. Beginning from the 5th day after infection the females release (over a period of 4–16 weeks a total of 2,000 larvae (3), which hatch from their eggshell while still inside the single uterus (UT). The hatched larvae (LA) measure about 100 × 8 μm and are characterized by rounded poles and an extremely long esophagus; they eventually enter the wall of the intestine and are carried away by the hepatic portal system through the liver, heart, and lung, and thus are distributed by the arterial system throughout the body of the same host (which thus may act as final and intermediate host).

4 When larvae reach skeletal muscles, they penetrate individual fibers and begin to grow, reaching up to 1 mm in length (without molt); up to 7 larvae have been seen within a single fiber which is altered due to the parasitism. At first, the region around the worm becomes amorphous (due to disappearance of sarcomeres) and finally a broad dense outer, but still intracellular, zone is produced, apparently by deposition of primarily metabolic material (AC) leading to some sort of a capsule. Outside this capsule thickening may be brought about infiltration of leukocytes and calcification (beginning about 10 months after infection). Such encysted worms are infectious for many years; transmission occurs again when such larvae are ingested by another omnivorous or carnivorous host. In the intestine excystation proceeds; however, the number and location of the following molts are still a matter of controversy. AC anlage of a capsule (at the inner periphery of an infected

the characteristics of which are depicted in Table 1.

Symptoms of Disease (Trichinosis, Trichiniasis)

Humans

About 1–2 weeks after the infection by ingestion of raw, larvae containing meat severe symptoms may occur during the early phase before larvae

enter the muscle fibers of the host. Strong infections lead to abdominal pain, vomiting, and diarrheas. As soon as larvae are produced in the host’s intestine and start to enter muscle fibers the following symptoms are seen (symptoms may already occur if only 70 larvae have entered):

- Edemas in the face, conjunctivitis
- Fever for a few days up to weeks
- Muscle pain, problems during breathing
- Pneumonia

region), HN host cell nucleus (unchanged), HY hypertrophied host cell nucleus, IN intestine, LA larvae, M mouth, MF muscle fiber (uninfected), MT muscle trichine, NR neural ring, OV ovary with eggs, RE ► testis, UT uterus, VU vulva

***Trichinella spiralis*
and Related Species,**

Fig. 4 Light micrograph of two squeezed muscle cells containing 3 larvae (*above*) respectively 1 larva (*below*) of *T. spiralis*

- Eosinophilia (up to 90 %)

Severely infected persons recover very slowly (even under successful treatment). Death cases occur due to pneumonia, cardiac and circulation problems, and (rarely) due to encephalitis or embolies.

Animals

The following symptoms of disease had been described in *Trichinella* infected animals in cases of strong infections. Infections with few worms remain often inapparent.

- **Pigs:** stiff walking, problem to swallow food, catarrhal enteritis, myositis.
- **Dogs, cats:** Diarrheas, vomiting, convulsions, cramps, swelling around eyes, heart problems.
- **Horses:** Problems to walk, eosinophilia, changing of several physiological parameters.

Diagnosis

Humans

Diagnostic measurements are mostly started in humans, when clinical symptoms occur or a high eosinophilia and/or a strong increase of the creatine kinase is diagnosed. The larvae in muscle fibers can be shown by the help of biopsy material after trypsin digestion or even by microscopical investigation of squeezed muscle material

***Trichinella spiralis* and Related Species,**
Fig. 5 Semithin section of a muscle fiber with a larva of *T. spiralis* being three times sectioned

(Figs. 3, 4, 5, and 6). At the very beginning of the muscle invasion phase larvae can be obtained by filtration of blood through a membrane or by help of Knott's concentration method (Fig. 3).

Trichinella spiralis and Related Species,

Fig. 6 Paraffin section of a HE-stained muscle fiber containing several cross sections of a larva of *T. spiralis*. Note that the center of the cell had already been dedifferentiated and thus appears granular, while the remnant cell shows the original muscle structure

Serological diagnostic tests (IIFT, ELISA, IHA) or PCR give significant results beginning about 1 week after infection (Fig. 7).

Animals

According to regulations of the European Community (EU: EG No. 853/2004; EG 2075/2005) all imported or exported meat of pigs and horses, which is used for human consumption, must be tested for *Trichinella* infection. This must be also done for meat of bears or boars. The method of choice is the trypsin digestion of muscle pieces and microscopical inspection for larvae. However, inspection for trichinosis is not obligatorily used in many countries.

Infection

Oral intake of raw or undercooked larvae containing meat. Since immunity after infections

remains low graded repeated infections are possible.

Prophylaxis

Avoid eating raw or undercooked meat. Eating deep frozen raw meat remains dangerous, since several species (e.g., *T. britovi*, *T. spiralis*, and *T. pseudospiralis* especially in horse meat) have developed a high tolerance against freezing.

Incubation Period

Depending on the amount of ingested larvae within raw or undercooked meat first symptoms occur after 1–28 days. Variations are also due to the different *Trichinella* species or even due to strain specificities.

Prepatent Period

Starting from days 5–7 after ingestion the females have reached maturity and start to produce larvae, which can be diagnosed inside blood.

Patency

At least 20 years; antibodies have been shown for up to 30 years.

Therapy

Humans

The therapy during the acute phase should start as early as possible. Albendazole (2×400 mg/day for adults, children 15 mg/kg bodyweight/day for 14 days), mebendazole (3×20 mg/kg bodyweight/day), and tiabendazole (2×25 mg/kg bodyweight) also for 14 days are efficacious. In case of severe infections, the additional use of corticosteroids is strongly recommended.

Trichinella spiralis and Related Species,

Fig. 7 Diagrammatic representation of the transformation of the muscle fiber after penetration of a *Trichinella* larva in four steps. (a) Just after penetration. (b) Formation of zones inside host cell. After destruction of sarcomeres nuclei become hypertrophic and many small mitochondria are accumulated along the surface of the larva. (c) The peripheral endoplasmic reticulum forms a zone of dense material. (d) Within 60 days the outer condensed layer is enormously enlarged. The parasitized cell may become surrounded by an additional (not drawn) layer of connective tissue cells. *CE* confluent ER, *ER* endoplasmic reticulum, *KA* wall of capsule = cyst wall, *KH* hypertrophied nucleus of the host cell, *KW* nucleus of host cell, *MI* mitochondria, *SD* sarcomeres in deformation, *TR* larva 1 of trichines, *WZ* host zell, *ZM* cell membrane

Animals

Young dogs and cats were cured by help of albendazole (50 mg/kg bodyweight twice a day for 7 days). Treatment of pigs or horses is in general not done (except for valuable animals).

***Trichinella spiralis*: Potential Paratenic Host**

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

► *Trichinella spiralis* and related species are regularly transmitted between carnivore hosts. Thus herbivores are normally not infected. However, if carnivore arthropods (beetles, larvae of beetles, and flies, etc.) ingest infected meat (e.g., of a dead mouse), they may ingest infectious *T. spiralis*. If these arthropods are then ingested by plant feeders (e.g., horses, roe deer), larval stages are produced inside their muscles. This explains numerous *T. spiralis*-infected horses in Europe.

Trichinelliasis, Man

Synonyms

Trichinellosis, Trichinosis

Pathology

Infection with ► *Trichinella spiralis* and several subspecies is acquired by ingestion of undercooked meat from pig, bear, walrus, and certain other omnivorous species (► Pathology, Figs. 18C, D-20). Encysted larvae in muscle are set free during digestion, and enter the intestinal epithelial cells where they become mature in the first week, generally giving rise to ► diarrhoea

and severe eosinophilic inflammation especially in reinfections. The worms mate and produce larvae which invade the intestinal wall and enter the bloodstream. After some migration, they enter skeletal muscle in the second and third week of infection. With heavy infection myositis, oedema, and high fever with ► eosinophilia. Make their appearance in the second week when larvae invade the muscle fibres in which they encapsulate (*Trichinella*, ► Pathology, Fig. 18C). Blood eosinophilic is pronounced 3–5 weeks after infection. Myocarditis and ► encephalitis may result from transitory worm migration. While the larvae grow intracellularly, the muscle fibres form an inner capsule and an outer capsule, the endomysium, which becomes hyalinized. The coiled larvae may persist for many years. Calcium may be deposited in the capsule and muscle and eventually the larvae dies (► Pathology, Fig. 18D). Eosinophilic inflammatory foci caused by occasional degenerating larvae are found in muscles.

Immune Responses

Within 10–15 days *Trichinella* are completely removed from the intestine of infected rats or mice. The worm loss is associated with profound inflammatory changes such as infiltration of the mucosa with mast cells, villus atrophy and crypt ► hyperplasia, net secretion and accumulation of fluid in the gut lumen, and increased peristalsis. These changes in the environment appear to make the intestine inhospitable to the worm, so that it is no longer able to maintain its preferred position in the small intestine. The inflammatory changes are dependent upon the local activation of CD4⁺ Th2 cells that develop in the lamina propria and draining mesenteric lymph nodes. These cells do not mediate worm expulsion by themselves, but instead promote the differentiation and activation of mast cells. Several experimental findings support this scenario: (1) Nude mice and mast-cell-deficient mice allow prolonged *Trichinella* persistence and restoration of mast-cell responses restores the ability to expel worms, (2) worm loss correlates with the release of mucosal mast

cell-specific proteases, and (3) blocking mast-cell development with antibodies against c-kit (stem cell factor receptor) prevents worm expulsion. Th2 cytokines such as IL-3, IL-4, and IL-9 participate in the development of a protective mastocytosis. The accompanying infiltration of the mucosa with eosinophils could be blocked by treatment of mice with anti-IL-5 antibodies. The finding that this treatment did not stop worm expulsion suggests, that if eosinophils do have a role it is not essential.

Unexpectedly, it has been recently shown that IL-4 is not only required for worm expulsion but also involved in the development of enteropathy. Moreover, abrogation of severe pathology in TNF-receptor-deficient mice did not prevent parasite expulsion. These findings suggests (1) a novel interplay between IL-4 and TNF and (2) that IL-4-mediated protection operates by mechanisms other than merely the gross degradation of the parasite's environment as a consequence of immune enteropathy.

The role of antibodies in worm expulsion is questionable. Passive transfer experiments suggest that IgA and IgG antibodies may interfere with worm growth and reproduction, but do not directly cause worm loss during primary infections. Experience of a primary infection with *Trichinella* however leads to a dramatically faster expulsion of worms following a secondary infection. This is associated with a number of electrophysiological changes in the epithelial cells of the mucosa which are induced by IgE- and IgG bound to mucosal mast cells leading to an anaphylactic reaction mediated via 5-hydroxytryptamine.

Main clinical symptoms: ► Abdominal pain, diarrhoea, ► vomiting, ► oedema, fever for days to weeks, muscle pain, eosinophilia.

Incubation period: 1–28 days.

Prepatent period: 5 days.

Patent period: 20 years.

Diagnosis: Serodiagnostic methods, microscopic determination of larvae in muscle biopsies (► *Trichinella spiralis*, Fig. 5), ► Serology.

Prophylaxis: Avoid eating raw meat.

Therapy: Treatment see ► Nematocidal Drugs, Man.

Trichinelloscopy

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This is a method employed to detect infections with ► *Trichinella spiralis* in pork muscles by depressing a small piece of the muscles of the diaphragm. Muscle larvae will become visible when examining the slide by the help of light microscopy. Trichinelloscopy was worldwide used in Prussia (an eastern region of Germany around 1850, when the famous scientist Virchow initiated trichinelloscopy by law, since many people died during these times due to ► trichinellosis. Today diagnosis on *Trichinella* infection of porks is done at all only in a few numbers of countries (e.g., Germany). Today portions of muscles of about 10–20 pigs are digested together by trypsin incubation, and after centrifugation the sediment is examined by the help of a light microscope for *Trichinella* larvae. In case of a positive result, each pig of the group is controlled separately in order to find out the infected ones, which then will be taken out.

of a mature stage

Classification

Genus of the subphylum ► [Ciliophora](#) (belonging to the protozoan phylum Alveolata)-classis: Oligohymenophorea, order: Mobilida.

Morphology

Species of the genera *Trichodina* (Ø 60 µm), *Trichodinella* (Ø 40–50 µm), *Tripartiella* (Ø 40 µm), etc., live as ectoparasites on the skin and/or gills of many fresh and saltwater fish, but also on hydrozoan or anthozoan polyps (e.g., *T. pediculus* = louse of polyps). The trophozoites look like a depressed cylinder and show bunches and rows of cilia at both sides. At the ventral side they develop species-specific circles of hooks, which are used as holdfast organs to become attached at the surface of their hosts, where they move in slight rotations (Figs. 1, 2, and 3). At high infection rates (in mass productions of fish or on

fish with other diseases), the symptoms of trichodinosis may become severe ► [Flagella](#).

Protazol of Alpha-Biocare, Düsseldorf.

Trichomitris

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Trichomitris is a genus of polymastigote flagellates parasitic in the intestine of termites.

Trichomitus rotundus

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This trichomonadid species is found in the cecum of pigs; infection is probably due to trophozoites in food and drinking water. Other species are found in reptiles and amphibia. These species are claimed to be involved in occasionally occurring diarrheas.

Trichomonadid Flagellates in Human Mouth and Intestine

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

In the mouth, cecum, and colon of humans, a spectrum of apathogenic flagellates has been described, which appear as well as free-flagellated stages but also as cysts, which can be diagnosed, when methods like flotation or SAFC and MIFC were used, respectively. Their number is generally low; it may become enlarged in case of immunosuppressed persons (Figs. 1 and 2):

1. *Trichomonas tenax*: This parasite, which occurs in the mouth of humans, reaches a length of up to 16 μm (Fig. 1).
2. *Pentatrichomonas hominis* (Fig. 2c, d): The stages of this species reach in the intestine with a size of 8–20 μm in length and possess five anterior flagella and a recurrent one, which reaches to the posterior end of the cell.

Trichomonadid Flagellates in Human Mouth and Intestine, Fig. 1 Diagrammatic representation of *Trichomonas tenax*

A typical axial rod is present appearing as a long spike at the posterior pole.

3. *Enteromonas hominis* (Fig. 2g, h): The flagellated stage reaches a length of 5–10 μm and possesses three anterior flagella plus a short recurrent one. It forms cysts.
4. *Chilomastix mesnili* (Fig. 2a, b): This flagellate lives in the intestine and appears in two stages: one with free flagella and a recurrent one in a slight groove channel, respectively. The second stage has retracted its flagella. An axial rod never occurs.
5. *Retortamonas intestinalis* (Fig. 2e, f): The specimens are either flagellated (with two flagella) or are flagella-less. In general they are very tiny with a length ranging between 4 and 9 μm . They do not possess an axial rod.
6. *Dientamoeba fragilis* (Fig. 2i, j): See ► [Dientamoeba fragilis](#) entry.

Trichomonadid Flagellates in Human Mouth and Intestine, Fig. 2 Diagrammatic representations of flagellates within the human intestine. (a, b) *Chilomastix mesnili*, (c, d) *Pentatrichomonas hominis*, (g, h)

Enteromonas hominis, (i, j) *Dientamoeba fragilis*. AX axostyle, B basal body, CO costa, F flagellum, N nucleus, NV food vacuole, RA remnants of axostyle, RF recurrent flagellum, RFI reduced RF, ZW cyst wall

Trichomonadida

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Order of ► [Mastigophora](#).

General Information

Apart from the genera *Histomonas* (one free flagellum) and *Dientamoeba* (no flagellum), the trichomonadids listed in Table 1 are provided at their apical pole with 4, 5, or 6 free ► [flagella](#) and an additional recurrent flagellum (Figs. 1, 2)

which runs along a surface wave giving rise to the aspect of an ► [undulating membrane](#) (Fig. 1, RF). Further characteristics of ► [trichomonads](#) are the ► [axostyle](#), pelta, ► [costa](#), and parabasal bodies, which serve as ► [cytoskeleton](#) (Figs. 1, 2).

The trichomonads, which are anaerobic, have ► [microbodies](#) called ► [hydrogenosomes](#). They are limited by two closely attached membranes surrounding a granular matrix (Fig. 1c, e). The enzyme system of these bodies differs from that of ► [mitochondria](#), as they metabolize pyruvate from ► [glycolysis](#) into acetate, CO₂, and H₂. (In ciliates, similar hydrogenosomes with double membranes are present, in addition to regular mitochondria, Figs. 1, 2).

The cytostomeless trichomonadids feed by phagocytosis on the fluids of their hosts, on leukocytes, or on bacteria. Reproduction occurs by a special form of longitudinal ► [binary fission](#) (Cell Division), leading to large numbers of

T

Trichomonadida, Fig. 1 A-E SEMS (A, B) and TEMS (C-E) of *Trichomonas vaginalis* (B-E) and *Tritrichomonas foetus* (A). Note that in *T. foetus* the recurrent flagellum runs until the posterior pole (compare Fig. 2). The axostyle

► **trophozoites** in a short time; cysts never occur, so transmission is always based on direct contact between the final sites of parasitism (e.g., copulatory organs, mouth, or fresh intestinal contents).

Among the trichomonads there are nonpathogenic, facultatively pathogenic, and regularly pathogenic species closely related to each other.

► *Histomonas meleagridis*, ► *Trichomonas vaginalis*, and ► *Tritrichomonas foetus* cause diseases of considerable importance (Table 1).

Important Species

Table 1.

Trichomonadida of Animals

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name: Greek (*tri*, three; *thrix*, hair; and *monas*, organisms).

The specimens of the group of flagellated protozoans live in the sexual organs and excretory system of their hosts. They are characterized by a specific number of free flagella and often possess

Trichomonadida, Fig. 2 Some variously flagellated trichomonads of man and animals; transmission proceeds directly by sexual intercourse or close body contact, respectively; cysts do not occur. Note that besides the free anterior flagella (AF) there is always a characteristic recurrent flagellum (RF); it often runs along a surface folding and thus appears with some sort of “undulating membrane”. 1 *Tritrichomonas foetus* from genital organs of cattle (10–20 μ m long). 2 *Trichomonas vaginalis* from

reproductive tracts of men and women (10–30 μ m long). 3 *T. tenax* (5–16 μ m long) from human mouth. 4 *T. gallinae* (5–20 μ m long) from mouth, pharynx, and crop of many birds. 5 ► *Pentatrichomonas hominis* (8–20 μ m long) from human intestine. AF anterior free-flagellum, AX axostyle, CO costa, HY hydrogenosome, N nucleus, PB parabasal body, PG parabasal body and ► **Golgi apparatus** (seen together), RF recurrent flagellum (for other species see Table 1)

Trichomonadida, Fig. 1 (continued) (AX) and pelta (PL) consist of single rows of microtubules (A, B $\times$ 3000, C $\times$ 6000, D $\times$ 34,000, E $\times$ 33,000). AX axostyle, B basal body of F, CO costa, ER endoplasmic reticulum, F free flagellum, FV food vacuole, H hydrogenosome, MT microtubules, PB parabasal body (filament), PL pelta, RF recurrent flagellum, U undulating membrane (formed by surface)

Trichomonadida of Animals, Table 1 Important species of the order Trichomonadida

Species	Size µm	Parasitized organ	Characteristics	Symptoms of disease	Hosts

<i>Trichomonas gallinae</i>	7–15 × 5–10	Crop, cecum, colon, inner organs	4 FF, 1 RF	Severe breakdown	Many bird species
<i>Trichomonas gallinarum</i>	9 × 5	Cecum	3 FF, 1 RF	Axostyle shiny	Chicken, turkeys
<i>Histomonas meleagridis</i>	5–30	Intestine, cloaca, internal organs	1–4 FF, cysts	Severe breakdown	Many bird species
<i>Trichomonas</i> -, <i>Tritrichomonas</i> -, <i>Pentatrichomonas</i> species	10 × 15	Intestine	3, 4, or 5 FF, 1 RF	Often inapparent	Amphibia, reptiles
<i>Trichomonas ovis</i>	9 × 6	Rumen, cecum	4 FF, 1 RF	Inapparent	Sheep
<i>Trichomonas suis</i>	16 × 8	Small intestine	4 FF, 1 RF	Inapparent	Pigs

FF free flagella, RF recurrent flagella

an additional recurrent flagellum, which is attached at some places of the single limiting membrane of these parasites. The stability of the cell body is often reached by the formation of a so-called ► **axostyle** (see ► *Trichomonas vaginalis*), which consists of one to several rows of microtubules, which make the specimens appear with a pointed terminal pole. The species of birds, cattle, horses, donkeys, camels, etc. are of veterinary importance, since they may introduce severe diseases (see examples in Table 1).

Trichomonads and Their Cell Biology

S. B. Gould, G. Kusdian, V. Zimorski and
W. F. Martin
Institut für Molekulare Evolution,
Heinrich-Heine-Universität, Düsseldorf,
Germany

General Information

Trichomonads are unicellular eukaryotes (protists) and belong to the order Trichomonadida

within the phylum Parabasalia that contains only anaerobic species. In current higher-level eukaryote systematics, the parabasalids are placed within the kingdom Excavata. Because of their anaerobic lifestyle, many trichomonads inhabit the gut of cockroaches or termites, and many are important parasites that infect a wide range of vertebrate hosts (see below Table 1). All trichomonads possess a single nucleus situated at the anterior end of the cell (Fig. 1). A characteristic feature of the parasite’s cytoskeleton includes the costa, pelta, and axostyle – together often referred to as the mastigont system. The costa is a thick filamentous rod composed out of large striated fibres that opposes the undulating membrane on the cytosolic side. The pelta is a microtubule-based structure that supports the canal from which the flagella emerge. It localizes within the mastigont system at the apical end of the cell. The axostyle is a rigid, longitudinal microtubular structure which localizes along the cell median and can exceed the trophozoid cell shape at the posterior edge without passing the cell membrane.

The various species of Trichomonadida carry 4–6 flagella that emerge from the region of the pelta. One specific flagellum among these is known as the “recurrent” flagellum. It is attached

Trichomonads and Their Cell Biology, Table 1 Selected trichomonads of human and veterinary importance. The most common representatives of the Trichomonadida, their hosts, locations, and corresponding diseases

Trichomonad species	Host	Location in host	Disease

Trichomonads and Their Cell Biology, Fig. 1 A free-swimming, pear-shaped *Trichomonas vaginalis* cell showing the typical morphology. The nucleus (*N*) sits at the anterior end of the cell in close proximity to the pelta (*PL*). Four anterior flagella (*AF*) emerge from the pelta region. The “recurrent flagella” runs alongside the cell’s entire surface and is attached to the undulating membrane

(*UM*), which is supported on the opposed side of the plasma membrane by the costa (*C*). Throughout the cell median, the axostyle (*AX*) is located, often exceeding the posterior end, while still being enwrapped by the plasma membrane. The energy (ATP)-producing hydrogenosomes (*H*) often cluster around the axostyle but can also freely float within the cytosol

to the undulating membrane that runs along the entire cell surface toward the posterior end. The undulating membrane is supported by the costa and is another characteristic feature of Trichomonadida.

The best-studied trichomonad is *Trichomonas vaginalis*, a parasite of the human urogenital tract. It is the causal agent of trichomoniasis, which is the most widespread sexually transmitted nonviral disease in humans that primarily afflicts women.

Upon contact with vaginal epithelial tissue, the rigid free-living free-swimming pear-shaped cell undergoes a rapid transformation in cell shape into an amoeboid-adherent cell. This change in cell shape is called the amoeboid transition. The amoeboid *Trichomonas* cells feed upon epithelial cells by phagocytotic ingestion of cell fragments. This is the basis of their parasitic lifestyle within humans. The amoeboid transition is a rare mechanism that has been described for only a few members of the Trichomonadida and for a few other protists, including the parasite *Naegleria gruberi* and the free-living form *Physarum polycephalum*. This morphogenesis is important for its infection and shows strain-specific traits. The transition is completed within minutes and the resulting amoeboid cells exhibit a highly dynamic amoeboid-adherent gliding motility that directs them toward host cells while forming pseudopodia in the process. In eukaryotic parasites studied so far, the actin-based cytoskeleton is the key component of this gliding locomotion. (Kusdian et al. 2013).

Trichomonads typically do not form cysts. In unfavorable environmental conditions, they have been reported to form reversible “pseudocysts” by internalizing their flagella, but these observations remain isolated and remain controversial. Trichomonad reproduction is achieved by a process called cryptopleuromitosis. It is a special form of longitudinal fission and closed mitosis; the nuclear envelope remains intact during cell division, and the spindle apparatus attaches to the outside of the nucleus.

All members of the Trichomonadida possess anaerobic forms of mitochondria called hydrogenosomes. Like mitochondria in vertebrates, hydrogenosomes are separated from the cytosol by a double membrane; they import pyruvate and generate ATP for the cell via pyruvate breakdown. But in contrast to vertebrate mitochondria, hydrogenosomes are devoid of a genome and translation machinery, lack cytochromes and a respiratory chain, and produce ATP solely through substrate-level phosphorylation, releasing hydrogen as a by-product. Clinical treatments for trichomoniasis exploit the biochemistry of pyruvate breakdown in hydrogenosomes.

Trichomonas vaginalis was identified as a member of the ten most important eukaryotic human pathogens in 2000. It was a prime target for genome sequencing funded by the NIAID/NIH (National Institute of Allergy and Infectious Diseases/National Institutes of Health). *Trichomonas vaginalis* is the only species among Trichomonadida whose genome has been sequenced. In 2002 the sequencing project commenced and was officially released in 2007. The genome size of 160 Mbp remains the largest protist genome so far sequenced, approximately encoding 60,000 proteins distributed on six chromosomes. In comparison, the human genome size is roughly 15 times larger but contains only about 25,000 protein-coding genes. Roughly 65 % of *T. vaginalis*' genome consists of repetitive sequences, which were likely generated during the large-scale genome duplication events subsequent to the evolutionary divergence of *T. vaginalis* and *T. tenax*.

The anaerobic energy metabolism of *T. vaginalis* is fermentative under aerobic as well as anaerobic conditions, using the cytosolic Embden-Meyerhof-Parnas type of glycolysis and carbohydrate as the main energy source (Müller 2003). The glycolytic end-product pyruvate is then imported into hydrogenosomes, which then produce 1 mol each H₂, CO₂, and acetate along with 1 mol ATP per mol pyruvate via substrate-level phosphorylation. Trichomonads are not able to synthesize amino acids de novo with the exception of cysteine. Accordingly, they must obtain all amino acids for protein synthesis and growth from their host. The genome harbors a large number of genes encoding aminotransferases which might allow them to use amino acids as supplemental energy substrates.

Like in all Trichomonadida, reproduction of *T. vaginalis* is asexual. Proteins specific to meiosis are encoded and expressed by the parasite, but neither meiosis nor gamete fusions have yet been observed. Laboratory cultures are reported to sometimes have quadri-nucleated cells. It is possible that meiosis and sex were recently lost in the parasite's history or that both exist but are either not observed or not recognized under conditions that have been studied.

Much current research focuses on the molecular machinery behind pathobiology of *T. vaginalis* with the goal of developing better treatments. It is known that *T. vaginalis* surface proteins mediate adherence to host cells, whereby these surface adhesion proteins – adhesins – are separated into three classes: the BspA family, the glycocalyx proteins, and a heterogeneous class of proteins called adhesins. The BspA protein family members have been localized to the parasite's surface, whose exact function remains elusive. There are over 900 identified members of the BspA gene family in the *T. vaginalis* genome, encoding proteins with a variety of different repeat regions, such as leucine-rich repeats and glycine-rich domains, with 191 copies furthermore encoding at least one membrane-spanning region. The second class of surface adhesion proteins is the components of the thick glycocalyx that surrounds the *T. vaginalis* cell and that is thought to directly interact with the host extracellular matrix. For one member of this class, the interaction partner of the host tissue has been identified: the human galectin-1. The third and most puzzling class of surface adhesion proteins is called adhesins. These include many of the most highly expressed proteins in the cell, including enzymes of the glycolytic pathway and enzymes of substrate-level phosphorylation inside hydrogenosomes. The mechanisms that might allow these proteins of energy metabolism to have dual roles at the cell surface are not yet known. Host-parasite interactions furthermore include microvesicles secreted by *T. vaginalis* that are thought to prime the host cell for parasite attachment. They have physical and biochemical characteristics similar to mammalian exosomes and fuse with host cells to modulate their cell immune response.

Clinical Relevance

Because of their medical and veterinary importance, *Trichomonas vaginalis* and *Tritrichomonas foetus* are the two best-studied species among

trichomonads. *T. foetus* afflicts cattle; infections can cause mild vaginitis or cervicitis but also abortion and infertility, causing significant losses for the global beef industry.

Like chlamydia, gonorrhea, and syphilis, *T. vaginalis* is a nonviral and sexually transmitted infectious agent. It annually infects an estimated 190 million people worldwide, while 85 % of the cases occur in developing countries. The majority of infections are primarily asymptomatic, and only a few result in trichomoniasis. However, infected women can suffer from vaginal discharge, vulval itching, and abnormal vaginal odor, whereas urethritis and prostatitis or prostate cancer are the corresponding diseases occurring among infected men. During acute infections of *T. vaginalis*, women are also reported to have pelvic inflammatory disease and adverse pregnancy outcomes, including preterm delivery and low birth weight. Additionally, trichomoniasis is thought to increase the transmission of HIV by local accumulations of HIV-infected cells such as lymphocytes and macrophages. The initial diagnosis of trichomoniasis is problematic. The standard diagnostic tool for *T. vaginalis* detection is wet mount microscopy, which is known for its low sensitivity as well as its limited use for female samples only. However, culture, antibody, and nucleic acid-based technologies for detection are improving.

Treatment

Trichomoniasis is usually treated with 5-nitroimidazole derivatives such as metronidazole and tinidazole, both well-established drugs. Metronidazole is selectively active against anaerobic organisms and equally affects anaerobic bacteria and parasites. Metronidazole is incorporated by *T. vaginalis* via passive diffusion and subsequently activated by nonenzymatic reduction in the hydrogenosomes. The mechanism of activation involves low-potential electrons stemming from hydrogenosomal metabolism. This

activation generates nitro radicals which are locally toxic to the *Trichomonas* cells by interfering with proteins and their trafficking. However, metronidazole-resistant strains were first reported in 1959, and their number is on the rise. Resistance is currently found among 2.5–10 % of the strains tested. The enzyme flavin reductase 1 appears to play a significant role in these resistant strains due to its downregulation. Furthermore, metronidazole resistance seems to be associated with single-nucleotide polymorphisms in nitroreductase genes *tnntr4* and *tnntr6*.

Conclusions

The trichomonads harbor some of the best-studied eukaryotic anaerobes. Free-living species have the ability to live as endosymbionts in cockroaches or termites; parasitic members of this group have found access to a large variety of host species, including birds (*T. gallinae*), cattle (*T. foetus*), and humans (*T. vaginalis*). The history of trichomonad pathogenicity has recently been traced back to the Jurassic period through the finding of *T. gallinae*-like lesions in the fossil mandible of dinosaurs.

Trichomonas vaginalis is the causative agent of trichomoniasis – a widespread, underdiagnosed, and often asymptomatic disease – with implications for birth-related prematurity, fetal loss, and increased HIV transmission and acquisition. Derivatives of 5-nitroimidazole are the only established and most effective drug against *T. vaginalis*. Metronidazole-resistant strains are known. Metronidazole is activated by enzymes of metabolism in hydrogenosomes. Because hydrogenosomes lack a genome, all proteins are encoded by nuclear genes and imported into the organelle.

Current knowledge about the proteins that reside within the *T. vaginalis* hydrogenosome is scarce. Based on proteomics data, it has been estimated that there are approximately 500 hydrogenosomal proteins. From the two

proteomic reports currently available, only 127 proteins overlap, however, and fewer than 50 proteins have been experimentally validated as hydrogenosomal. In this respect, knowledge about the identity of hydrogenosomal proteins lags far behind that of respiring mitochondria. The proteomes of the two organelles are qualitatively very different, as many hydrogenosomal proteins do not have a mitochondrial homologue and vice versa. There is an ongoing effort to understand how pathways diverged between hydrogenosomes and mitochondria. When hydrogenosomes were first discovered in 1973, there were no proteins common to mitochondria and hydrogenosomes. Now, all proteins involved in hydrogenosomal metabolism are known to occur in the respiring mitochondria of at least one eukaryotic group (Müller et al. 2012). This underscores the common ancestry of mitochondria and hydrogenosomes and their evolutionary specialization to aerobic and anaerobic niches.

Alternative approaches to *Trichomonas* treatment might include prevention of its amoeboid transition. Studying gene expression of the parasite during infection or oxygen stress revealed up- and downregulation of different genes, which might point to key steps during pathogenesis. Not only the anaerobic metabolism but also the cytoskeletal-associated proteins of *T. vaginalis* might be the targets for future drugs as well.

Vaccination against *Trichomonas* has long been under investigation. Some success has been reported for mouse model systems, but for humans no vaccines have been developed. One future approach might entail whole-cell vaccines, which are simple and cost efficient, but carry risks of possible autoimmunity from multiple antigens evoking molecular mimicry in host defense. A proton-pump inhibitor drug against trichomonads was recently introduced that inhibits the ability of the parasite to utilize nucleic acid components from the host. There are also studies of the natural polyphenol resveratrol (RESV) on *T. vaginalis*, which indicate that concentration between 25 and 100 μM inhibited the in vitro

growth of trophozoites through inhibition of a 120-kDa [Fe]-hydrogenase. Curcumin, a secondary metabolite of the Asian spice *Curcuma longa*, has also shown some promises for treatment of *T. vaginalis* infections.

- attached to the epithelium and its slimy layers) the upper intestinal tract (e.g., crop, esophagus), reaches a size of 7–15 $\mu\text{m} \times 5\text{--}10\text{ }\mu\text{m}$, appears pear shaped, and is characterized by four free anterior flagella and a recurrent one (Fig. 1, left side). The axostyle initiates a visible protrusion at the posterior pole of the cell. Reproduction occurs by longitudinal binary fission. Hosts are pigeons, chickens, and many free-living birds.
- (b) *Tetratrichomonas gallinarum*: This species has been observed in chickens, turkeys, and related species. It is characterized by four free anterior flagella and a recurrent one (Fig. 1, right side), which does surpass the posterior pole. The parasites have a length of about 8–10 μm .

Trichomonas and Tetratrichomonas Species of Birds

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *tri* = three; *thrix* = hair; *monas* = organism. Latin: *gallus* = chicken; *columba* = pigeon.

Geographic Distributions/Epidemiology

Worldwide, some strains are very virulent and thus may endanger chicken farming. Up to 60 % of the birds may be infected.

Morphology/Life Cycle

- (a) *Trichomonas gallinae* (syn. *T. columbae*) (Fig. 1, left): This species parasitizes (being

Symptoms of Disease (Trichomoniasis)

- (A) The infection with *T. gallinae* results in three (strain specific) diseases/groups of symptoms:
- Throat-crop-form (called yellow-button): the symptoms are yellow diphtheroid covers (Fig. 2) on the mucous layers in the upper alimentary system, which hinder an easy drinking and feeding. Thus the animals do not feed enough, lose weight, and get weakened. In case of “carrier/racing pigeons,” their flight range is strongly reduced.
 - Inner generalized form: here are seen spot-like covers on inner organs: heart, liver, lung, and air sacs. These symptoms often lead to death or at least to increased morbidity.
 - Infections of navels: this leads to reduced food uptake, loss of weight, and is characterized by slimy masses in nestlings.
- (B) Infections with *T. gallinarum* may introduce diarrheas (the feces of the ceca appear yellowish and are fluid). In rare cases also generalized infections of many other organs have been seen.

**Trichomonas
and Tetratrichomonas
Species of Birds,**

Fig. 1 Diagrammatic
representations of stages of
T. gallinae and
Tetratrichomonas
gallinarum (Redrawn and
colored after Cheng/
Soulsby)

Diagnosis

Microscopical examinations of vital preparations or Giemsa-stained smear preparation of the slimy contents (Fig. 3).

Infection

Oral uptake of flagellates from infected animals by feeding fecally contaminated grains or drinking water.

Prophylaxis

Three steps are recommended:

1. Early spring treatment: adult birds should be treated (see Therapy).
2. Treatment of any new bird that is added to a stable.

Trichomonas and Tetratrichomonas Species of Birds,
Fig. 2 Photo of diphtheroid layers in the throat of a pigeon

**Trichomonas
and Tetratrichomonas**

Species of Birds,

preparation

3. Avoiding the contact of own birds with wild ones; regular cleaning of soils and drinking vessels.

Incubation Period

1–4 days.

Prepatent Period

4 days.

Patency

Years.

Therapy

- (a) Never scrape off the slimy covers – otherwise strong bleedings occur.
- (b) Lesions at the navel have to be thoroughly disinfected.
- (c) Treatment with 5-nitroimidazoles via drinking water for 6–12 days or even for 20 days. Ronidazole was described as very helpful.

Trichomonas tenax

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek (*trichos* = tiny, thin hair; *monas* = simple organism and Latin (*tenere* = keep, hold fast).

Geographic Distribution/Epidemiology

Worldwide, especially in persons with reduced oral hygiene.

Morphology/Life Cycle

T. tenax occurs only as flagellated, vegetative stage in the oral cavity of humans reaching a length of 5–16 μm . This stage possesses four free flagella at the anterior pole and a lateral recurrent one (Fig. 1). Reproduction occurs by repeated longitudinal binary fission. They feed on bacteria, which they ingest by phagocytosis. However, they ingest also masses of glycogen from food remnants in the teeth. Mass reproduction occurs in cases, when the oral microflora has increased due to low oral hygiene. Intestinal passage is apparently not survivable for these specimens.

Symptoms of Disease

There are really no signs of a peculiar activity as agent of disease, although trophozoites were found already in the lung and trachea.

Diagnosis

Microscopical investigation of plaque samples diluted in 0.85 % NaCl.

Trichomonas tenax,
Fig. 1 Diagrammatic representation of *T. tenax* from the human mouth

Infection

Common use of drinking water and kissing interactions of persons.

Prophylaxis

Intense oral hygiene, eat only few amounts of sugar.

Incubation Period

Unknown.

Prepatent Period

Unknown.

Patency

Months during poor oral hygiene.

Therapy

No special treatment necessary – oral hygiene products will kill these organisms.

Trichomonas vaginalis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *trichos* = thin hair; *monas* = simple organism. Latin: *vagina* = female genital opening

Geographic Distribution/Epidemiology

Worldwide, around 500 million people are infected, often at the same time with fungi (*Candida*) and/or bacteria (e.g., *Streptococcus*, *Enterococcus* species); infection rates are especially high in cases of unprotected sexual intercourse with often changing partners.

Morphology/Life Cycle

T. vaginalis (Figs. 1, 2 and 3) lives in the fluids of the vagina and cervix of females and of the preputium, prostate glands, and urethra of males and belongs to the group of flagellate protozoans.

Trichomonas vaginalis, Fig. 1 Diagrammatic representation of *Trichomonas vaginalis*. AF free flagella; A axostyl; CO costa; HY hydrogenosomes; N nucleus; PB parabasal body; PG parabasal body plus golgi; RF recurrent flagellum

It appears pear shaped and measures about 10–25 μm in length and is characterized by four free flagella starting at the apical pole and a recurrent flagellum which is attached at the lateral side. Furthermore, a so-called axostyle structure stretches from the anterior pole (where it surrounds the nucleus) until the very end of the cell, where it leads to the appearance of a pointed tip. The axostyle consists of a layer of parallelly running microtubules. Besides the axostyle, other organelles such as costa and parabasal bodies support the stabilization of the *Trichomonas* cell, since this parasite is limited only by a single membrane. This membrane ruptures very easily, if the *Trichomonas* cells get in contact with freshwater or even seawater outside the body (e.g., in swimming pools). The feeding occurs by phagocytosis of bacteria or components of destroyed

Trichomonas vaginalis,**Fig. 2** Light micrograph of *T. vaginalis***Trichomonas vaginalis, Fig. 3** Scanning electron micrograph of a trophozoite of *T. vaginalis*

cells inside the human genital system. *T. vaginalis* possesses no mitochondria but obtains its energy by complicated processes inside organelles, which are called ► [hydrogenosomes](#). These organelles are presented in a separate chapter.

Under certain – not yet fully understood – conditions, the normal speed of reproduction by longitudinal binary fission is considerably increased, so that masses of those flagellates are found inside the genital systems of male or female humans. Cysts do never occur in the life cycle of *T. vaginalis* – also not in tissue cultures, which can be easily kept for years. *T. vaginalis* possesses about 60,000 genes – the largest number in protozoans – which help to adapt and to survive in diverse changes of their environment in hosts.

Symptoms of Disease (Trichomoniasis)

The incubation period may need – depending on the initial infection doses and the predisposition of the vaginal or preputial fluid – up to several weeks or infections may even remain undiscovered. In low-rate infections, the following symptoms occur: a light burning (itching) feeling during urine deposition and increased strangury. In case of infections of females, a whitish-greenish-yellowish foamy slime may take possession in the vagina. In case of pelvic inflammatory events (reddish vulvovaginitis, etc.), i.e., when bacteria or fungi enter the vessels of the urinary system or enter the oviducts, disease may become acute and introduce severe damages. For example, the oviduct lumen may become closed, and thus sperms cannot pass to eggs, or bacterial infections may

destroy kidneys. In male patients, the symptoms are mostly rather mild so that they remain often undiscovered. This is very important, since these persons do not know that they may transmit *T. vaginalis* during unprotected sexual intercourse. In rather rare cases, however, also males had shown severe symptoms of disease (e.g., prostatitis or epididymitis) as consequences of the coexistences of bunches of *T. vaginalis* stages, bacteria, and eventually fungi.

Diagnosis

Microscopic analysis can be done by immediate investigation of a droplet of vaginal slime being diluted by 0.85 NaCl solution. The parasites are recognized by their staggering movements. In case of low-graded infections, cultures are recommended. The Giemsa staining shows the cytoplasm of the flagellates in a slight blue, while the nuclei and flagella appear red (Fig. 2). For differential diagnosis, the difference to leucocytes is needed. Standard serological tests like KBR, IIFT, or ELISA bring high-rated security in such infections. However, in cases of mild asymptomatic or low-grade infections, cultures bring best results (e.g., Diamond's medium).

Infection

Infection occurs exclusively during unprotected sexual intercourse. Transmission via water of swimming pools is excluded, since the flagellate cannot survive – even not for a minute – in water. However, contact of swimsuits in drying trunks in natatoria to slime from other people may be a source for an infection.

Prophylaxis

Avoid unprotected sexual intercourse with foreign persons.

Incubation Period

Four to twenty-four days.

Prepatent Period

Four to twenty days.

Patency

Months or even years under insanitary conditions or due to repeated ping-pong infection from one partner to the other.

Therapy

It is absolutely necessary to treat both sexual partners at the same time (!). Especially in consideration that also parallel infections with fungi (*Candida*) or bacteria may be present, use of nitroimidazole (e.g., metronidazole) is recommended. As a single dose 2 g or 2×500 mg daily for 7 days is recommended by several authors. However, in up to 5 % of the cases, metronidazole resistance occurs. In these cases, the doses should be increased to up to 4 g/day, or tinidazole should be used (4×500 mg daily for 14 days). Also, ornidazole and secnidazole are effective.

The scanning electron microscopy shows clearly the 4 free flagella and the attached 5th one. Note also the terminally protruding axostyl (See Fig. 1).

Trichomoniasis Treatment Progress

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Infections by ► *Trichomonas vaginalis* are very often not recognized and/or unsuccessfully treated. Thus, a broad spectrum of substances (chemical and biological) had been tested. Effects were summarized in the paper of De Brum Vieira et al. (2015).

References

De Brum VP et al (2015) Natural and synthetic compound anti-*Trichomonas vaginalis* : an update review. *Parasitol Res* 114:1249–1261

Trichomoniasis, Man

► *Trichomonas vaginalis* is a flagellate, 10–30 µm in size, a pale-staining nucleus, 4 free ► flagella, and an ► undulating membrane (► *Trichomonadida*). It lives in the vagina and prostate gland. It is best recognized supravivally by its motility or in a smear. Trichomoniasis gives rise to acute and chronic vaginitis accompanied by a neutrophil exudate and a change in bacterial flora. Infection is chronic, but if cured by chemotherapy reinfections can occur giving rise to renewed symptoms. Immunity in the vagina appears to be poor. Cervical dysplasia is occasionally observed but appears to be the result of concomitant infection with one of the papilloma viruses. Males may have infection in the prostate gland which is usually asymptomatic but is accompanied by acute and chronic inflammation. *T. tenax* from the mouth and *T. hominis* from the gut are regarded as commensals.

Main Clinical Symptoms

Occurrence of whitish mucus (fluor), feeling of burning in vaginal and urethral regions.

Incubation Period

4–24 days.

Prepatent Period

4–20 days.

Patent Period

Months – years.

Diagnosis

Microscopic detection of ► trophozoites in mucus samples.

Prophylaxis

Avoid unprotected sexual intercourse.

Therapy

Treatment see ► Antidiarrhoeal and Antitrichomoniasis Drugs.

Trichosomoides crassicauda

Species of nematodes (females, 10–19 mm; males, 1–3 mm), the specimens of which live in groups in the urinary bladder, ureter, kidney of hare, rabbits, and rodents. Eggs have small polar plugs. The larvae enter the stomach wall and penetrate into the blood vessels.

Trichostrongylidae

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *thrix*, *trichos* = fine hair; *strongylos* = rounded; *nema* = filament, thread; *oncos* = hook; *phorein* = carry. Latin: *contortus* =

coiled; *circum* = around; *cinctus* = with a belt; *tela* = tissue; *custus* = shortened; *colubriformis* = snake-like; *filicollis* = with a tiny neck; *helvetianus* = from Swiss; *dorsum* = back.

Robert von Ostertag and C.F. Cooper = helminthologists.

Geographic Distributions/Epidemiology

The here-included nematodes occur worldwide in practically all plant-feeding vertebrates except for fish. They live – depending on the species – in the stomach (abomasum) and/or in the small intestine often in huge numbers, which may induce local epidemics.

Morphology/Life Cycle

Species in Ruminants

The different species of the trichostrongylids live in the abomasum or in the small intestine of their hosts (Fig. 1; Table 1). Since the clinical symptoms and the morphological appearance of the different species are not species specific, the different species are not separately presented here. This way of presentation is also supported by the fact that differential chemotherapy is not needed.

(a) Large stomach worms

Haemonchus contortus and related species (Table 1) occur in the abomasum of cattle, sheep, and goats as well as in many wild ruminants. They lie on the mucous layer of the abomasum, suck blood, and thus appear reddish (with translucent whitish gonad tubes). Females reach a length of up to 30 cm, males of 20 cm. Characteristics are two hook-like cervical plates at the anterior end (Fig. 2). The bursa copulatrix of males has two basal lobes and an asymmetric dorsal one. The spicula have the same length and may be protruded to become injected into the female vulva which is situated 3–5 mm before the terminal pole and is covered by a valve.

(b) Small stomach worms and intestinal worms

- *Ostertagia* species and *Teladorsagia* species (Table 1) are rather small, whitish-appearing worms which are enclosed in nodules (Fig. 3) or are found attached at the surface of the abomasum. The males reach a length of up to 9 mm, the females up to 13 mm. The spicula of the males are short but have both the same length. Their bursa copulatrix has three lobes. The vulva of the females occurs in the terminal fifth of their body length, being covered in some species by a valve.
- *Cooperia* species (e.g., *C. oncophora* – cattle; *C. curticei* – sheep; Table 1) appear as fine, tiny reddish worms (rarely reaching more than 9 mm in length). The spicula of the males are short, and the vulva of the females is located in the terminal fourth of the body. The anterior end is often spirally coiled, and the cuticle shows ring-like waves.
- *Trichostrongylus* species parasitize in the abomasum and in the small intestine. They measure about 2.5–7 mm at the maximum and appear as tiny reddish-brownish, anteriorly pointed worms with a typical annulation of their cuticula. The two spicula of the males have a different length, and the vulva of the females is situated in the posterior half of the body.
- *Nematodirus* species occur in the small intestine and appear thread like. Males reach a length of 1.7 cm, females 2.5 cm. The spicula of the males are very long (1.5 mm), and the vulva of the females is located in the posterior half of the body, which shows in both sexes a linear cuticular protrusion at the anterior pole.

The life cycle is diagrammatically depicted in Fig. 1. It is important that larva 1 hatches from the egg in all species (except for those of the genus *Nematodirus*) and develops on the soil into larva 3, while in *Nematodirus* this development occurs inside the excreted egg. Most eggs measure

Trichostrongylidae, Fig. 1 (a) Life cycle of trichostrongylid [nematodes](#) of different hosts. 1 Adults ([► Nematodes/](#)Table 1) live attached to the villi of abomasum or small intestine (species-specific) and feed on blood (e.g. *Haemonchus*). 2 Smooth-walled eggs are passed unembryonated in host's feces. 3 Larvae are developed under favourable conditions inside the eggs. 4–7 Except for [► Nematodirus](#), the L1 hatches from the egg and feed

on detritus. After 2 molts the L3 stage is achieved which is infective to final hosts. These third-stage larvae, still wearing the loosely fitting second stage [► cuticle](#) (= sheath), climb to the top of plants (7) and may even hibernate outside a host. 8–9 If final hosts swallow the L1 with forage, the exsheathment takes place in the stomach. The larvae of some species may burrow into the mucosa and molt there twice; larvae of other species molt when

70–98 × 30–50 μm (except for *Nematodirus*: 150–180 μm × 67–77 μm) and are rather thin walled, containing 16 or already more cells. The larvae are long living, and thus meadows remain contaminated for long. Larvae of *Nematodirus* species hatch from eggs only in next spring, when being deposited in autumn. Larvae 3 ingested in autumn show a “sleeping” phase inside their hosts and start further development only in next spring. Thus, they stay in a so-called ► **hypobiosis** stage. On the other side, many species in spring excrete increased numbers of eggs. This behavior is called “spring rise phenomenon.”

Trichostrongylids in Other Animals

(a) **Horse/equids:**

Trichostrongylus axei (♀ = 8 mm; ♂ = 6 mm) lives in the stomach. The strongylids of horses have a direct life cycle (See ► **Trichostrongylosis, animals**).

(b) **Pigs:**

► *Hyostrongylus rubidus*; these worms (♀ = ~12 mm; ♂ = 7 mm) live in the stomach, suck blood, and thus appear reddish and have a direct life cycle.

(c) **Rabbits/hares:**

► *Graphidium strigosum* (♀ = 2 cm; ♂ = 1.5 cm) and *Obeliscoides cuniculi* both live in the stomach, while *Trichostrongylus retortaeformis* is found in the small intestine.

(d) **Birds:**

Trichostrongylus tenuis (♀ = 9 mm; ♂ 6 mm) are found in the small intestine and in the ceca appear reddish, and their development is direct.

Symptoms of Disease

The intensity of the symptoms of disease depends strongly on the number of parasitizing worms plus their way of feeding, since blood suckers induce in general more serious problems. Especially young animals in their first meadow period suffer severely. Main symptoms are apathia, watery and smelling diarrheas, loss of weight, edemas, hydraemia, anemia, anorexia, swelling of lymph nodes, heavy breathing, fever, and eventual death. **Attention:** Some trichostrongylids have also a zoonotic potential.

Trichostrongylidae, Table 1 Important Trichostrongylids

Species	Female size (mm)	Location	Prevalence rates		
			Cattle	Sheep	Goats
<i>Haemonchus contortus</i>	20–30	Abomasum	+	+++	+++
<i>Ostertagia ostertagia</i>	8–12	Abomasum	+++	+	+

Trichostrongylidae, Fig. 1 (continued) attached to the villi. In some species (e.g., ► *Ostertagia*) the fourth-stage larvae may hibernate inside the mucosa for 3–5 months; this phenomenon is described as ► **hypobiosis**. In spring these L4 complete their development and become mature after another molt. The increased excretion of eggs is

known as ► **spring rise phenomenon**. (b) The anterior (1) and posterior (2–8) regions of infective larvae (L3) of different genera parasitizing sheep, according to several authors. ES oesophagus; L3 third-stage larva; NR nerve ring; SH sheath (cuticle of the preceding larval stage)

Trichostrongylidae, Fig. 2 Scanning electron (a, b, d) and light (c) micrograph of the anterior and posterior end of a female worm of *Haemonchus contortus* (a, c) and *Oesophagostomum* sp. (b, d)

Diagnosis

Microscopic demonstration of the eggs after use of concentration methods (e.g., ► [flotation](#); S.A.F.C.).

Infection

Oral uptake of sheathed larvae 3, which are attached to grass.

Prophylaxis

Change of meadows; see ► [Chemotherapy](#).

Incubation Period

About 14 days; in case of ► [hypobiosis](#), next spring.

Trichostrongylidae, Fig. 3 Macrophoto of a trichostrongylid nodule in the intestinal wall of a cattle

Trichostrongylidae, Fig. 4 Scanning electron and light micrographs of the anterior end of a *Trichostrongylus* worm. *BU* bulbus; *CUS* striation of cuticle; *M* mouth; *O* oesophagus; *SO* sense organ; *UE* uterus filled with eggs

Prepatent Period (Examples)

- *Haemonchus contortus*: 18–24 days (Fig. 2)
- *Ostertagia* sp. 18–23 days;
- *Trichostrongylus* sp. 17–21 days (Fig. 4)
- *Teladorsagia* sp. 16–18 days
- *Cooperia* sp. 14–22 days
- *Nematodirus* sp. 15–26 days
- *Marshallagia* sp. 21–32 days
- *Skrjabinagia* sp. 18–20 days

Patency

Species-specific periods ranging from a few days, e.g., 30–40 days (*Nematodirus*) up to months or years (e.g., in *Trichostrongylus*).

Therapy

Chemotherapy/chemoprophylaxis: Treatment should be done about 4–6 weeks after animals had been placed on the meadow; further treatments should be done in July/August and in autumn. Benzimidazoles show a broad variety of resistances, while macrocyclic lactones (used in different ways, e.g., spot on, bolus application, etc.) are highly effective.

Trichostrongylosis, Animals

Stomach

► *Trichostrongylus axei* worms occur in the stomach of horses and rarely in pigs. These ► **nematodes** are rarely pathogens on their own, most infections are chronic and mild. However, *T. axei* induces typical lesions in horses. The condition has been described as a *gastritis chronica hyperplastica et erosiva circumscripta* for the main lesion is a pad- or cushion-like thickening in the glandular part of the stomach.

Abomasum

T. axei lives in the abomasum of cattle, sheep, and goats. In ruminants, *T. axei* infections are usually part of a mixed abomasal helminthosis and its effects cannot be dissociated from those of other worm species. The worm is rarely a pathogen on its own, as most infections are mild. Animals experimentally infected with large numbers of *T. axei* show a decrease of blood albumin, haemoconcentration, and a rise in serum pepsinogen. The clinical signs include ► **diarrhoea**, ► **anorexia**, progressive emaciation, Listlessness, and weakness.

Small Intestine

Some members of the genus ► *Trichostrongylus* parasitize the anterior part of the small intestine of ruminants, and are particularly important in sheep. The most common species in sheep and goats are *T. colubriformis* (also found in cattle), *T. vitrinus* and *T. rugatus*. *T. vitrinus* appears to be more pathogenic than the other 2 species. They all cause a similar syndrome which may range in intensity from a subclinical but significant loss of production to overt disease. Trichostrongylosis is characterized by anorexia, soft faeces, intermittent or continued diarrhoea, ► [weight loss](#), listlessness, and osteoporosis in growing lambs. Severely affected animals become dehydrated and some may die. Changes in blood constituents include a light ► [anaemia](#), hypophosphataemia with normocalcaemia, and a characteristic ► [hypoalbuminaemia](#). A reduction in thyroxine concentrations and an increase in circulating levels of alkaline phosphatase of intestinal origin has been reported in chronic cases.

Although considerable progress has been achieved in our understanding of the physiopathology of *Trichostrongylus* parasites, it is still difficult to explain the signs of trichostrongylosis. Practically all stages of the parasite live in tunnels beneath the epithelial cells of the intestine, causing mucosal and villous atrophy or flattening. Sparse stunted ► [microvilli](#), epithelial ► [hyperplasia](#) are also present, with infiltration of lymphocytes and neutrophils in the damaged area. This atrophy leads to a reduction of the effective glandular mass and of the levels of brush-border enzymes (notably dipeptidase, alkaline phosphatase, and maltase). In addition, there is evidence that the parasite alters the levels of gut hormones (e.g., secretin and cholecystokinin) and induces a progressive inhibition of abomasal, duodenal, and cranial jejunal motility, which reduces the passage of digests. Potential causes of diarrhoea, when it occurs, may be an alteration in ruminal and abomasal functions, increased plasma loss into the intestine, or other effects of the worm on water, Na⁺ and osmotic loading of the small intestine. The decrease in productivity does not appear to be related to malabsorption, since net

absorption of nutrient over the length of the small intestine is not severely affected. It is rather, caused by the combination of loss of appetite, enteric losses of protein, and increased protein metabolism in the intestinal tissue, which all together cause a movement of amino acid nitrogen from the muscle, and possibly the skin, to the liver and intestines. This decreases the possibility for growth, and production of milk and wool. The reduction in feed intake is the main factor limiting the availability of energy for maintenance and/or growth. Another reason for the less efficient use of metabolic energy is the marked increase in synthetic rates of blood proteins and proteins in the gastrointestinal tissue, to compensate for the losses of plasma protein into the alimentary tract and for the increased sloughing of epithelial cells. The reduced mineralisation of bones leading to osteoporosis in growing lambs may be attributable to reduced intestinal absorption of calcium and phosphorus.

Trichostrongylus

Name

Greek: *thrix*, *trichos* = fine hair, *strongylos* = rounded.

Classification

Genus of ► [nematodes](#).

General Information

Trichostrongylus spp. occur in ruminants and horses (e.g., *T. axei*, *T. vitrinus*, *T. colubriformis*), rabbits (*T. retortaeformis*), and birds (*T. tenuis*). They are tiny worms (often not reaching 1 cm in length). Together with the members of the genera *Haemonchus*, ► *Teladorsagia*, ► *Cooperia*, ► *Nematodirus*, ► *Ostertagia* they are placed in the nematode family Trichostrongylidae. Their individual number is often very large, because the infections occur on the meadow, while uptaking larva-contaminated plants (p. 1476).

Trichuriasis, Animals

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

► *Trichuris* spp., the whipworms, inhabit the cecum and occasionally the colon of ruminants. The most important species are *T. discolor* and *T. globulosa* in cattle, *T. suis* in pigs, and *T. ovis* and *T. skrjabini* in sheep and goats. ► *Trichuris* is highly prevalent in all parts of the world but rarely causes clinical signs. Heavy infections associated with severe and often hemorrhagic typhilitis or typhlocolitis has been rarely reported in cattle. Clinical manifestations include ► *anorexia*, dysentery, ► *conjugation*, ► *weight loss*, and terminal ► *anemia*. In severe cases, the feces may be markedly hemorrhagic or even all blood. The lesions are caused by the adult worms boring tunnels into the mucosa of the large intestine. Penetration of the mucosa by the parasites produce ► *nodules* in the intestinal wall. There is little evidence that *Trichuris* spp. of ruminants ingest measurable quantities of blood. The signs of the disease appear to be primarily related to a reduction of the absorption capacity of the colon, an effusion of protein into the lumen, and a loss of blood through hemorrhages.

Trichuriasis, Man

Pathology

Trichuriasis is an infection with a small lumen-dwelling ► [whipworm](#) ► *Trichuris trichiura*, of worldwide distribution. The thin anterior end of the worm is embedded in the epithelium of the colon from which it ingests intercellular fluids. Depending on the degree of infection, the degree of inflammation produced may be severe, with a mixed inflammatory reaction and with bloody mucus, containing eosinophils and ► [Charcot-Leyden crystals](#) (► [Pathology](#)/Fig. 3). Rectal prolapse from tenesmus has been described in heavily infected children. Although it does not actively suck blood, the daily blood loss was calculated as 0.005 ml per worm, supporting its role in causing anemia in iron-deficient children together with malnutrition.

Immune Responses

Nematode Infections, Man/Immune Responses.

Main Clinical Symptoms

Red-diarrhoea, ► [anaemia](#), colitis, ► [eosinophilia](#).

Incubation Period

2–3 months.

Prepatent Period

3 months.

Patent Period

15–18 months.

Diagnosis

Microscopic determination of eggs in faecal samples (► [Trichuris](#), Fig. 4).

Prophylaxis

Avoid eating uncooked vegetables and contact with human faeces.

Therapy

Treatment see ► [Nematocidal Drugs, Man](#).

f female, m male

Trichuris, Fig. 1 Life cycle of whipworms (e.g., *Trichuris trichiura*, *T. ovis*) as examples of a direct development. 1–2 The adult male and female worms (4–8 cm long) are anchored with their slender anterior ends inside the mucosal layer of the cecum, colon, and/or rectum of their hosts. After fertilization, the females produce numerous (3,000–7,000 daily) eggs (each with two polar plugs) which measure about $70\text{--}90 \times 30\text{--}40 \mu\text{m}$ and are passed unembryonated in the feces of their hosts (2). 3–9 On the soil, the zygote slowly develops into the first-stage larva (7) which remains inside the egg for this embryonation; at least 3 weeks (up to 4 months) are needed (dependent on the temperature). Finally (still inside the egg), the second larval stage (8) is formed and reaches infectivity. (Some

authors, however, consider eggs containing the first-stage larvae as already infectious.) When eggs including infectious larvae (8) are swallowed with contaminated food, the second larval stage escapes from the egg within 60 min (in the duodenum). Via 3 following molts the typical adult worm is finally formed, reaching maturity in about 5–9 weeks (Prepatent Period), it may parasitize for 1–4 years (Patent Period). Trichuris serrata

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

T. serrata is a nematode of the cecum and upper large intestine of cats and was first described by von Linstow (1879). Subsequent morphological descriptions have been inconsistent with some descriptions indicating that *T. serrata* can be distinguished from *T. campanula*, the other species in cats, by the presence of a vulvar projection and bacillary band and others indicating that size can

Trichuris, Fig. 5 *Trichuris suis* egg with the two typical polar plugs and the already formed larva

be used to distinguish the species (Ng and Kelly 1975). It also has been postulated that there is only one species in cats (Bowman et al. 2002). Most hosts only have one *Trichuris* species, and, therefore, it has been suggested that *T. serrata* and *T. campanula* should be considered one species named *T. felis*.

Identification of *Trichuris* spp. is problematic due to the morphological variations within species. Callejón et al. (2013) and Kelzis et al. (2015), however, obtained helpful PCR characteristics to show that two different species exist.

Trichuris Species of Animals

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek (*thrix*, *trichos* = hair; *ura* = tail), Latin (*ovis* = sheep, *sus* = pig, *vulpes* = fox, *mus* = mouse, *lepor* = hare, *discolor* = two colors), and English (whipworm) (due to the tiny anterior end).

Geographic Distribution/Epidemiology

Worldwide in farmed animals and in wild relatives, in cases of many animals in close neighborhoods in stables, massive epidemics may occur.

Morphology/Life Cycles

The following species are very common:

<i>T. vulpis</i> (dogs, foxes)	♀/♂ = up to 7.5 cm
<i>T. suis</i> (pigs)	♀/♂ = up to 4.5 cm
<i>T. discolor</i> (ruminants)	♀/♂ = up to 4–8 cm
<i>T. ovis</i> (sheep)	♀/♂ = up to 4–8 cm
<i>T. leporis</i> (hare, rabbits)	♀/♂ = up to 3 cm
<i>T. muris</i> (rodents)	♀/♂ = up to 2.5 cm
<i>T. serrata</i> , <i>T. campanula</i> , <i>T. felis</i> (cats)	♀/♂ = up to 5 cm
<i>T. skrjabini</i> (ruminants)	♀/♂ = up to 8 cm
<i>T. globulosa</i> (ruminants)	♀/♂ = up to 8 cm

The adult worms (Figs. 1 and 2) possess a long, tiny anterior portion and a thick posterior one, so that they appear like a whip. The tiny anterior portion is anchored in the mucous layer of the ceca and of the colon, where the mouthpart even penetrates the interior of the epithelial cells and/or into tiny blood vessels. The females excrete the typical eggs, which are provided with two polar plugs at a non-embryonated stage (Fig. 3), which can be found in the feces.

Symptoms of Disease (Trichuriasis)

Since these worms destroy cells and small blood vessels and suck blood, the intestinal walls show edema and blood may occur in the feces. Thus in cases of mass infections, symptoms such as anemia, weight loss, weakness, slowing down of the development, dizziness, etc., are common, while

Trichuris Species

of Animals, Fig. 1 Light micrograph of an adult *T. suis* worm showing the tiny coiled anterior half and the posterior thickened region thus giving the impression of a whip

**Trichuris Species****of Animals,**

Fig. 2 Scanning electron micrograph of an adult *T. suis* worm showing the tiny coiled anterior half and the posterior thickened region thus giving the impression of a whip

**Trichuris Species**

of Animals, Fig. 3 Light micrograph of a *Trichuris* egg. Nonembryonated stage

Trichuris Species of Animals, Fig. 4 Light micrographs of *Trichuris* eggs. (a and b) Eggs of different species including the larva 1

low-graded infections may remain symptomless. However, *T. suis* eggs are used to ameliorate symptoms of Morbus Crohn and ulceritis, since these larvae stimulate the immune system of these patients.

Diagnosis

Microscopical determination of the typical brownish eggs, which possess a translucent protruding polar plug at each pole (Figs. 3 and 4). The eggs, which are excreted unembryonated when seen in the feces, can be concentrated by help of S.A.F.C. or ► [flotation](#) methods. Outside of the body, the larva 1 (Fig. 4) is formed inside the eggshell with a temperature-dependent time of up to one week. The eggs of the different species show similar measurements:

<i>T. vulpis</i>	70–90 × 30–40 μm
<i>T. suis</i>	65 × 30 μm

(continued)

<i>T. ovis</i>	70–80 × 25–40 μm
<i>T. muris</i>	70 × 35 μm

Infection

Oral uptake of eggs containing an infectious larva.

Prophylaxis

Regular deworming of farmed animals and strict regular elimination of the feces (before the larva is formed in the egg).

Incubation Period

First symptoms may already occur during the growing phase of the larva in case of mass infections. In general symptoms occur within 1–2 weeks; in case of *T. suis*, it takes mostly 6 weeks until symptoms of disease are diagnosed.

Prepatent Periods

<i>T. vulpis</i>	11–15 weeks
<i>T. suis</i>	8 weeks
<i>T. ovis</i>	7–12 weeks
<i>T. muris</i>	8–9 weeks

Patency

<i>T. vulpis</i>	1.5 years
<i>T. suis</i>	6 months
<i>T. ovis</i>	1 year
<i>T. muris</i>	3–4 months

Therapy

Depending on the host species, benzimidazoles or macrolytic lactones are used.

Trichuris Species: Hosts

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

About 70 *Trichuris* species have been described so far since the year 1761. Their definitive existence is recently a matter of molecular biological investigations, since transmission experiments are only done for a few species and decisive morphological criteria are weak.

Species	Hosts	Region
<i>T. campanula</i>	Cats, felids	Worldwide
<i>T. capreoli</i>	Deer, cattle	Europe, Asia
<i>T. discolor</i>	Cattle, ruminants	Worldwide
<i>T. globulosa</i>	Camels, ruminants	Worldwide
<i>T. leporis</i>	Hares, rabbits, <i>Citellus</i> sp.	Europe, America
<i>T. muris</i>	Mice, rats	Worldwide
<i>T. myocastor</i>	Beavers	Europe
<i>T. ovis</i>	Sheep, goats, cattle, camels, wild ruminants	Worldwide
<i>T. serrata</i>	Cats	America, Asia
<i>T. skrjabini</i>	Sheep, goats	Worldwide
<i>T. suis</i>	Pigs	Worldwide
<i>T. sylvilagi</i>	Rabbits, hares	Europe, USA
<i>T. trichiura</i>	Humans	Worldwide
<i>T. vulpis</i>	Dogs, foxes	Worldwide

Trichuris suis Artificial Larval Hatching

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The larvae of *Trichuris suis* – whipworm of pigs – can be used to stimulate the immune system of humans and thus block for up to 3 months of autoimmune reactions which lead to symptoms such as Morbus Crohn or ulcerative colitis. In cases of treatment, about 2,000 larvae-containing eggs have to be swallowed within some milliliter of water. In order to control, whether a sufficient number of larvae hatched and remained motile inside the intestine, a so-called hatch test must be done from time to time with stored eggs. By the way the larvae of *T. suis* do not reach maturity in humans, but die within 3 months after hatch. The process needs the following steps:

1. Incubation of the eggs in a 13 % hypochlorite solution at 40 °C and 5 % CO₂ for 2–5 h
2. Washing and centrifugation (1,000 rpm) within a *Trichuris*-hatching medium (see below)
3. Treatment with ultrasonic waves for 1 min
4. Transfer of treated eggs into plastic wells with hatching medium at 37–40 °C
5. Microscopical inspection of probes obtained from the wells (Figs. 1, 2, and 3)

Hatching Medium

- 450 ml RPMI 1,680 medium
- 50 ml fetal calf serum
- 5 ml 1 % hypochlorite solution
- 5 ml L-glutamine

Trichuris suis Artificial Larval Hatching, Fig. 1 Light micrograph of an egg containing a larva of *T. suis*

Trichuris trichiura

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek (*trix/trichos*, hair; *ura*, tail), English (human whipworm).

Geographic Distribution/Epidemiology

About 600–800 millions of humans are infected worldwide.

Morphology/Life Cycle

The adult worms, which reach in both sexes a length of up to 5 cm, are characterized by an anterior filament, a flagellar-like anterior portion, and a grip-like posterior one (Fig. 1). The anterior end is used to become attached at the mucous layer of the cecum and colon and to enter even cells. As in the group of trichines, the esophagus is lined by the so-called ► **stichosomal cells**; ► **nematodes**. The typical eggs, which measure about $50 \times 25 \mu\text{m}$, appear brownish and are characterized by two typical translucent polar caps. They are excreted within the human feces and develop at temperature of about 25°C within 3–4 days the infectious larva, which may remain infectious for years outside of a body. If such eggs are swallowed by humans, the larva hatches and reaches maturity within 1–3 months (Fig. 2).

Symptoms of Disease

Low-graded infections remain mostly subclinical, whereas heavy infections are characterized by bloody-slimy diarrheas followed by anemia, colitis, and eventually rectal prolapse. Blood examinations show additional eosinophilia.

Diagnosis

The eggs are especially characterized for the whole genus, but not for the different species ($50\text{--}55 \times 20\text{--}25 \mu\text{m}$).

***Trichuris trichiura*,**

Fig. 1 Macrophoto of an adult *Trichuris trichiura* worm

***Trichuris trichiura*, Fig. 2** Light micrograph of a typical egg of *T. trichiura* containing already a larva

Infection

Oral uptake of larvae containing eggs within contaminated food (e.g., unwashed salad). Due to absence of immunity, repeated infections are possible.

Prophylaxis

Avoid eating potentially fecally contaminated food.

Incubation Period

2–3 months.

Prepatent Period

3 months.

Patency

15–18 months.

Therapy

Drugs of choice are mebendazole (2×100 mg daily) and albendazole (1×400 mg daily) for 3 days. Children below 3 years: 15 mg/kg body weight for 3 days.

Further Reading

- Vercysse J et al (2011) Assessment of the anthelmintic efficacy of albendazole in school children in seven countries where soil transmitted helminthes are endemic. *PLoS Negl Trop Dis* 5

Trichuris vulpis

This worldwide occurring species in dogs and foxes reaches a length of 7.5 cm in both sexes in the caeca and colon of their hosts. Since the worms suck blood, oedema of the intestinal wall and bloody stools may occur in heavy infections, as well as anaemia, and loss of weight.

Trickle Infections

Application of low doses (given continuously at short intervals) of parasites to produce a persistent parasitic load in a given laboratory host. For examples, it is proven that *Nippostrongylus brasiliensis* given in this way produces large and persistent infections in rats and the normal spontaneous cure response does not occur. Trickle infections may establish worms even in immune hosts.

Triflumuron

Chemical Class

Benzoylphenyl urea.

Mode of Action

Insect growth regulator (IGR, chitin synthesis inhibitor). ► [Ectoparasiticides – Inhibitors of Arthropod Development](#).

Trimitis

Genus of intestinal flagellates of fish.

Trinotum anserinum

Species of ► [Mallophaga](#) of birds, vector of onchocercid worms.

Triodontolepis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Triodontolepis is a genus of hymenolepid tapeworms occurring in the intestine of European water shrews of the genus *Neomys*.

Triodontophorus serratus

Strongylid ► [nematode](#) of horses.

Tripartite Attachment Complex (TAC)

Filament system that connects the DNA of the kinetoplast (KD) of trypanosomes and the flagellas basal body (Fig. 1, p. 1484). This complex comprises unilateral filaments (F), differentiated mitochondrial membranes (M), and exclusion

Tripartite Attachment Complex (TAC), Fig. 1 DR of the filament system connecting the kinetoplast DNA and the basal body. (from Trends in Parasitology 2005, redrawn, coloured) *B* basal body, *DM* differentiated mitochondrial membrane, *E* exclusion zone filaments, *F* flagellum, *KD* kinetoplast DNA, *M* mitochondrion, *P* parabasal body, *UL* unilateral filaments

zone filaments (*E*). Both the TAC and the flagellar-system become reduplicated prior to cell division of the trypanosomal stages.

Tripartite Symbiosis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Symbiosis among three different organisms, e.g., termites, flagellates, bacteria.

Triphenylphosphate (TPP)

Chemical Class

Synergist.

Mode of Action

Detoxifying esterase inhibitor.

Tritonymph

The last of the three nymphal stages found in some members of the Actinedida and Acaridida (= Astigmata). By contrast, in most members of the Gamasida only proto- and deutonymphs occur.

The tritonymph is usually an active stage, but may be a pharate stage in some members of the Actinedida (► [Mites/Ontogeny](#)).

Tritrichomonas foetus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

1. **Name:** Greek: *tri* = three; *thrix* = hair; *monas* = organism. Latin: *fetus* = body fruit.
2. **Geographic distributions/epidemiology:** Worldwide, but relatively rare cases in Central Europe due to the recent practice of artificial insemination of cows. In countries with normal bull activity, there may occur epidemics, since clinical symptoms are seen only months after insemination. Thus, an infected bull may infect a large number of cows.
3. **Morphology/life cycle:** The parasite has a size of 12–18 × 6–10 μm, appears pear shaped, and possesses three free flagella and one recurrent flagellum (Fig. 1). The axostyle

***Tritrichomonas foetus*, Fig. 1** Scanning electron microscopic micrograph of trophozoites of *Tritrichomonas foetus*

leads to a pointed posterior cell pole. Another characteristic is also that the recurrent flagellum gets free at the posterior pole. The reproduction occurs by longitudinal binary fission and occurs in the case of cows inside the vagina, uterus, and oviducts, while in bulls the parasites are found in the preputium region and in the urethra. The parasites ingest bacteria and other cell components in the surroundings of their habitat, which are included in vacuoles during digestion. Trichomonads do not possess mitochondria to obtain energy but so-called hydrogenosomes.

4. **Symptoms of disease (Trichomoniasis):** In about 50 % of infected bulls, no symptoms are seen. This fact endangers cows during insemination! Cows show epidemic symptoms such as vaginitis and endometritis. Fluid slimes between yellow and green in color fill the cervix and vulva. Infections of the fetus lead often to fatal early birth about 6–16 weeks after insemination. Normally the fetus is pushed off; however, in cases where

the fetus becomes macerated (pyometra) inside the uterus, bacterial superinfections may endanger the life of cows.

5. **Diagnosis:** Demonstration of trophozoites in native fluids or in fixed Giemsa-stained preparations of freshly obtained fluids. Since in low-graded (initial) infections the number of parasites remains rather small, it is recommended to establish a culture and to repeat microscopic investigations. After a significant diagnosis, the veterinarian authorities have to be informed immediately. They will start the needed government regulations (depending on the situation in each country). In Germany, trichomoniasis of bulls is an epidemic, which has to be cleared by killing the infected bull.
6. **Infection:** Transmission of motile trichomonads occurs during insemination of cows by infected bulls. Cysts are never produced!
7. **Prophylaxis:** Use of sperms of healthy bulls; investigate freshly bought animals for this disease.
8. **Incubation period:** Varying length depending on the immune system of the animals.
9. **Prepatent period:** Weeks, variable.
10. **Patency:** Possibly years.
11. **Therapy:** Therapy only by veterinarians who know the legal situation.

Tritrichomonas foetus: SEM

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

This species of cattle is characterized by 3 free apical flagella and an attached lateral one (See Fig. 1).

***Tritrichomonas foetus*: SEM, Fig. 1** Scanning electron micrograph of a trophozoite showing the typical three anterior flagella

Tritrichomonas suis

Agent of pig trichomoniasis, probably identical with *T. foetus*. ► [Trichomonadida](#).

Trixacarus caviae

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Mite that introduces mange in guinea pigs and humans. Sites of infestation are the surroundings of the eye (“eye-glasses-appearance”) and other places at the head. This species belongs to the family of ► [Sarcoptidae](#) and reaches as adult length of about 150 µm.

Trochophora

Ciliated larva of many water inhabiting annelids (not present in ► [leeches](#)).

Troglostrongylus brevior

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Lungworm of cat, which first had been recorded from the respiratory tract of wild cats in Palestine, but now is also found in cats from Spain and Italy. The life cycle, which includes intermediate hosts such as slugs and snails as well as paratenic hosts such as lizards, birds, and small mammals, is very similar to that of ► [Aelurostrongylus abstrusus](#). *T. subcrenatus* is another lungworm of cats. Both induce symptoms, which range from subclinical to severe life-threatening conditions being featured by mucoid-purulent nasal discharge, sneezing, dyspnea, and anorexia. Their infectious larvae may survive for 4–5 months in the environment. Besides the infection via infected intermediate hosts, a different pathway is also possible – if the queen transmits larvae 3 within mother’s milk or if these larvae pass through the placenta.

***Troglostrongylus* Species**

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The species *T. brevior* and *T. subcrenatus* are lungworms of domestic and wild cats described

in Italy and in Palestine. They are metastrongylid worms and can hardly be differentiated from ► *Aelurostrongylus obstrusus* when only looking at morphological features. However, they are clinically of importance, since infected cats show severe symptoms of disease, which make a treatment necessary. Recent papers show that *Troglostrongylus brevior* does not only use the normal pathway of lungworm transmission (e.g., via an intermediate host) but also the direct way inside a cat queen via the placenta directly to the kittens (vertical transmission).

Trogocytosis

From Greek: *trogein* = to nibble. Way of feeding of ► *Naegleria fowleri*-amoebae.

Trojan Pathway of Infection

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes a hidden, but persisting, extremely low-graded infection of a host, which does not show any clinical signs but contains a small number of transmittable stages (e.g., tissue cysts of ► *Besnoitia besnoiti*, ► *Toxoplasma gondii* or single cystozoites of ► *Cystoisospora* species (e.g., *C. suis*, *C. felis*).

The descriptive name of this transmission is based on the tale of the Greek poet Homer on

the so-called Trojan War, during which Greek aggressors at first could not enter the city of Troja. Thus they left behind a wooden horse with hidden soldiers inside, who finally at night opened the doors of Troja after the horse had been transported into the town.

Transferring this tale to parasitology, the different parasites are spread in a similar way, when symptomless, but infected host animals are traded and thus transported to regions where a given parasite is not yet endemic.

Trombicula (syn. Leptotrombidium) akamushi

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek, *thrombos* = clot; the name refers to the appearance of this bloodsucking mite as a small bloody dot. This species is able to transmit in Asia the agents of the so-called tsutsugamushi fever (= scrub typhus). The agents belong to the species *Rickettsia tsutsugamushi* (syn. *R. orientalis*). These mites appear like the European mite ► *Neotrombicula autumnalis*.

Trophozoites

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *trophe* = food; *zoon* = animal.

Feeding stages of ► *Amoebae*, ► *Balantidium coli*, ► *Blastocystis hominis*, ► *Ichthyophthirius multifiliis*, ► *Plasmodium*, *Toxoplasma*.

Tropical Elephantiasis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Symptoms (enormous swellings of legs, arms, breasts, or scrotum) due to infections with filarial

worms, ► *Wuchereria* or ► *Brugia*, Lymphatic Filariasis.

Figures 1 and 2 show old photos of patients with swelling of the scrotum respectively breasts due to lymph node blockage induced by *Wuchereria bancrofti*. Photos from R. Koch's expeditions.

Tropical Parasitic Diseases of Man, Geographical Distribution

This group of diseases includes conditions the natural occurrence of which is largely limited to the tropics and the subtropics. This may be either

Tropical Elephantiasis, Fig. 1 Male patient with enlarged scrotum due to *W. bancrofti*

Tropical Elephantiasis, Fig. 2 Female patient with enlarged breasts due to filariasis

due to the specific temperature requirements for the survival or development of parasite forms in the free environment or in the poikilothermal vector or intermediate host, or due to the specific geographical distribution of the vector or intermediate host, again a feature that is dependent on environmental factors. This applies, inter alia, to African trypanosomiasis, falciparum malaria and ovale malaria.

However, the category includes also borderline cases such as diseases occurring mainly in the tropics and the subtropics, and at much lower frequency in temperate climates as well, e.g., opisthorchiasis, vivax malaria and malaria quartana. There are also diseases occasionally occurring outside the usual geographical distribution, e.g., sporadic cases of ovale malaria in south-eastern Asia. While the clinical picture resembles that of *Plasmodium ovale* infections contracted in Africa, the morphology of the parasites shows

characteristics of simian malaria parasites of the *P. ovale* group, pointing to a zoo-anthropotic origin analogous to the occasional human infections with *P. knowlesi* or *P. cynomolgi cynomolgi* observed in southeastern Asia.

Table 1 lists the major tropical diseases of man and excludes the cosmopolitan opportunistic parasitic infections in immunocompromised individuals such as patients with HIV infections. It should be noted, however, that also some tropical parasitoses show atypical pathology in such patients, especially marked in those trypanosomatid infections where amastigotes are responsible for the clinical-pathological lesions, i.e., visceral leishmaniasis and American trypanosomiasis. Moreover, *Leishmania* species usually responsible for cutaneous or mucocutaneous leishmaniasis, may cause visceral leishmaniasis (kala-azar) in patients with HIV infections, a phenomenon particularly marked in Sahelian Africa.

Tropical Parasitic Diseases of Man, Geographical Distribution, Table 1 Geographical distribution of major tropical parasitic diseases

Disease	Causative parasite	Vector/ alternate host	Geographical distribution
African trypanosomiasis	<i>Tryp. brucei gambiense</i>	<i>Glossina palpalis</i> group	Tropical west and central Africa

Paragonimiasis	~2,000,000	?	20	N.D.
Schistosomiasis	~10,000,000	60,000	100	1,760,000

*DALY = Disability adjusted life years (number of healthy years of life lost due to premature death and disability)
N.D. and ? = no data available

Tropical Parasitic Diseases of Man, Impact on Health

The major tropical parasitic diseases differ widely in the degree of impact on human life, ranging

between nearly 100 % fatality in the absence of treatment, such as in African trypanosomiasis, and a generally non-fatal course such as in lymphatic filariasis (see Table 1). In all cases the infections will have a detrimental impact on health as expressed in the ► [DALY](#) index, reflecting the

“disability adjusted life years,” i.e., the number of healthy years of life lost due to premature death and disability. Estimates for DALY are available for several of the most important tropical parasitic diseases, but not for others, especially those not yet covered by internationally supported control efforts.

Difficulties are also experienced in the determination of the number of deaths associated with particular parasitic infections, especially if they occur in areas with poor coverage by health services or if the infections give rise to fatal secondary pathological conditions such as cholangiocarcinoma. In the latter case the secondary condition is usually registered as the cause of death and not the truly causative infection with *Clonorchis* or *Opisthorchis*.

Some of the diseases have recently shown a remarkable change in morbidity and fatality, such as visceral leishmaniasis in association with HIV infections. The advent of HIV has radically changed the understanding of the epidemiology of leishmanial infections by indicating that oligosymptomatic carrier status largely outweighs the number of clinically manifest infections.

Other diseases, hitherto subject to rather successful attempts at their elimination, e.g., dracunculiasis, show lately unexpected persistence, having brought the control effort to a grinding halt in the last strongholds of their existence in tropical Africa. Disruptions by armed conflicts are obviously the major reason for the stalemate since the large majority of the recent dracunculiasis cases had occurred in areas affected by war or civil strife.

Tropilaelaps mercedesae

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Tropilaelaps mercedesae is a mite species that infects honeybees (*Apis mellifera*) in China.

***Truncatula* Species**

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Truncatula is a genus of snails, which serve as intermediate hosts for *Schistosoma mekongi*.

Trypanocidal Drugs, Animals

Wolfgang Raether¹ and Achim Harder²
¹Hoechst, Frankfurt, Germany
²Bayer HealthCare AG, Division Animal Health,
Leverkusen, Germany

Disease Patterns of African Trypanosomiasis

► **African trypanosomiasis** caused by tsetse-borne heteroxenous trypanosomes (*T. vivax vivax*, *T. congolense congolense*, and *T. brucei brucei*) is known as ► **Nagana**. Formerly the term was restricted to infections caused by *T. b. brucei*. Today, the term “trypanosomiasis” is also used as a collective word for all animal trypanosomiasis. The severity of disease may depend on several factors, such as trypanosome species, strain variants, infection dose (low or high tsetse risk), and species of host. Infections can vary from acute (*T. c. simiae* infections in pigs, *T. b. evansi* infections in camels) to usually mild or almost inapparent (*T. b. brucei* infections in cattle). In typical cases, African trypanosomiasis is a wasting disease with clinical signs like anemia, leucopenia, thrombocytopenia, plasma biochemical changes and lesions in some tissues and organs. The disease produces slowly progressive loss of condition accompanied by increasing weakness and extreme emaciation, leading eventually to collapse and death. *T. v. vivax* causes the most important form of trypanosomiasis in cattle in West

Africa and elsewhere. The infection may be asymptomatic, subacute, peracute or chronic. Hemorrhagic *T. vivax* outbreaks have been reported from farmers in Kenya and Uganda with considerable deaths of cattle. Symptoms were anemia, bleeding through the skin and ears (prior to death), petechial hemorrhages on the tongue, and enlarged spleen (for more information on hemorrhagic *T. vivax* see: Use of Drugs in the Field to Control Cattle Trypanosomiasis). *T. c. congolense* produces the most severe form of animal trypanosomiasis in East and Central Africa. Serious disease and death may occur in cattle, horses, and dogs. *T. b. evansi* also occurs in a dyskinetoplastic form in Central and South America (synonyms include *T. equinum* and *T. venezuelense*) where it is regarded as a separate species. *T. brucei equiperdum* produces a venereal disease (= ► [Dourine](#)) in equids (horses and donkeys) in Northwest Africa, Ethiopia, Central and South America, the Middle East, and Asiatic Russia. The disease is usually transmitted by coitus, and infrequently by biting flies or infective discharge. Apart from the typical salivarian or stercorarian pathway of infection any trypanosome can also be transmitted mechanically (e.g., artificially by “syringe passage”) without undergoing cyclical development in a vector as *T. vivax* infections of ruminant livestock in South and Central America. Noncyclical transmission can be done in nature by bloodsucking insects, such as ► [Tabanus](#) spp. and ► [Stomoxys](#) spp. flies (► [Diptera](#)). In South America ► [Vampire Bats](#) should also be a vector transmitting *T. brucei evansi* infections in horses. The disease is known as ► [Murrina](#) (Panama) or ► [Derrengadera](#) (Venezuela).

Economic Loss in Livestock

Economic loss due to cattle trypanosomiasis is difficult to assess, but the fact that livestock in Africa are treated with more than 30 million doses of trypanocidal drugs each year may give some indication of the importance of this problem. The impact of disease extends over approximately nine million km² of Africa between the southern

border of the Sahara in the north and the Limpopo in the south (sub-Saharan Africa), and threatens more than 50–70 million animals in 37 African countries. Partly a result of this disastrous situation is that Africa produces about 70 times less animal protein per unit area than Europe.

Dissemination of Trypanosomes in the Body of Host and Its Influence on Drug Action

There are two groups of tsetse-transmitted organisms, which can be distinguished: (1) the hematic group, including *T. c. congolense* and *T. v. vivax* and confined to the blood and lymphatic systems and (2) the humoral group, including *T. b. brucei*, *T. b. rhodesiense*, and *T. b. gambiense* (► [Trypanocidal Drugs, Man/Drugs Acting on African Trypanosomiasis \(Sleeping Sickness\) of Humans](#)). In addition to occurring in plasma, species of the humoral group are also present in body cavity fluids and intercellular tissue. Parasites of this group are parasitemic only in the terminal stages of the infection, and the chief pathological changes caused by these trypanosomes are extensive inflammatory, necrotic, and degenerative reactions (tissue damage), probably associated with release of kinins and fibrinogen degradation products. In contrast, parasites of the hematic group produce mainly a severe anemia, which determines the severity of disease. Although the anemias produced by *T. v. vivax* and *T. c. congolense* are equally serious, the mechanism of pathogenicity may be different for each species. *T. c. congolense* can also develop outside the circulatory system. Thus, the different distributions of the trypanosomes in the body of host result in varying susceptibilities to trypanocides depending on their pharmacodynamics (mechanisms of drug action) and pharmacokinetics (disposition and fate of drugs in the body). Relapse of infection, i.e., return of patent parasitemia after its apparent cessation by drug administration, may occur in chronic *T. b. brucei* infections (Trypanocidal Drugs, Man/Drugs Acting on African Trypanosomiasis (Sleeping Sickness) of Humans: late stage of

Trypanocidal Drugs, Animals, Table 1 Drugs used against trypanosome infections of domestic animals

Chemical group, nonproprietary name (approx. dose, mg/kg body weight, parenteral route) other information	* Brand name (manufacturer, company); other information; °first practical (commercial) use of drug	Characteristics (chemotherapeutic effects, adverse effects, miscellaneous comments)
Trivalent antimony complexes		
Potassium antimony tartrate (tartar emetic) (1–1.5 g i.v., repeatedly, 5 % aqueous solution) (3–6 g/100 kg i.m. or s.c. repeated doses required at weekly intervals) °1908	Therapeutic use antimosan, stibophen (sodium salt of antimosan)	The only satisfactory and cheap compound available prior to discovery of phenanthridine derivatives; it was useful for over 40 years in treating <i>T. c. congolense</i> and <i>T. v. vivax</i> infections in cattle and <i>T. b. evansi</i> infections in camels; extravascular
Injection causes severe necrosis; narrow chemotherapeutic index (about 6 % mortality in routine treatment); antimosan and stibophen were found to be effective against <i>T. c. congolense</i> and <i>T. v. vivax</i> but less against <i>T. b. brucei</i> ; it had been replaced by better tolerated drug products		
Sulfated naphthylamines		
Suramin (standard dose: camel, 10, slowly i.v., horse, three doses in 1 week; dog, dose may be repeated for several days) °1920	Therapeutic use *Germanin, *Bayer 205, *Naganium and others (Bayer) Suramin does not cross blood-brain barrier and is not active against secondary CNS stages of subgenus <i>Trypanozoon</i>	Developed by Bayer in Germany during the 1914–1918 war (Bayer 205); first report on <i>T. evansi</i> activity in 1925; shows high efficacy against trypanosomes of subgenus <i>Trypanozoon</i> (<i>T. b. brucei</i> , <i>T. b. evansi</i> , <i>T. equiperdum</i>) and <i>onchocerciasis</i> in man
(► Nematocidal Drugs, Man); drug of choice for <i>T. b. evansi</i> infections (surra) in camels and horses; it may be toxic in equines (slow i.v. injection) causing edema of sexual organs, lips, eyelids or painful hoofs; i.m. or s.c. administration can cause severe necrosis at injection site (beware paravenous injection); subdosing (less than 1 g/100 kg b.w.) may lead to suramin-resistant strains, which are usually sensitive to quinapyramine dimethylsulfate; drug is embryotoxic in mice and bound to almost 100 % to plasma proteins and slowly eliminated via kidneys; plasma t50 % is about 32 h, which may be problematic in animals intended for human consumption		
< Suramin (anhydrous) – quinapyramine sulfate complex>	Prophylactic use °1966 pig; °1971 horse	Strongly anionic suramin is able to form a sparingly soluble salt complex with cationic groups of other known trypanocidal drugs; as a result toxicity
Is reduced and prophylactic effect considerably prolonged; “depot effect” of suramin/quinapyramine against <i>T. b. evansi</i> infection in horses may last up to 6 months; it can be used prophylactically against <i>T. c. simiae</i> infections in pigs; trypanosomes resistant to the complex can be treated with isometamidium; mode of action is energy metabolism and hydrogen transport; it blocks NADH oxidation by inhibition of α -glycerophosphate dehydrogenase and oxidase		
Aminoquinolines		
Quinapyramine dimethosulfate (ruminants, pig, dog, 5, s.c.; equines, camel 3–5, s.c.; dose should be divided, and given at 6 h intervals because animals are more sensitive to drug than bovines °1949	Therapeutic use *Trypacide sulphate (Merial) *Antrycide (Alkaline Chemical Corp., India; Bella Trading Khartoum, Sudan) *Noroquine (Norbrook) *Quintrycide (Gharda) (usually used as a 10 % aqueous solution)	Is highly active against <i>T. c. congolense</i> , <i>T. v. vivax</i> , <i>T. b. brucei</i> , and <i>T. b. evansi</i> and reaches therapeutic levels quickly; drug can cause local and systemic reactions (salivation, shaking, trembling, diarrhoea, collapse) in cattle, horse, dogs, and pigs within minutes of treatment; effects resemble those of
Curare; stress (heat, fatigue, fear, etc.) should be avoided before and after treatment; unexpected acute toxicity and rapid development of drug-resistant strains of <i>T. c. congolense</i> have limited its operational area in treating trypanosomiasis in cattle; however, drug seems to be safe and efficient for treating surra (<i>T. b. evansi</i>) in camels and horses as well as <i>T. b. evansi</i> infections in pigs; quinapyramine-resistant strains are usually controlled by isometamidium; quinapyramine is active against suramin-resistant strains (<i>T. b. evansi</i> , <i>T. b. brucei</i>)		

(continued)

Trypanocidal Drugs, Animals, Table 1 (continued)

Chemical group, nonproprietary name (approx. dose, mg/kg body weight, parenteral route) other information	* Brand name (manufacturer, company); other information; °first practical (commercial) use of drug	Characteristics (chemotherapeutic effects, adverse effects, miscellaneous comments)
Quinapyramine dimethosulfate (water soluble) + chloride (insoluble in water) (3:2, w/w) (7.4, s.c.) °1950	Prophylactic (Therapeutic) use	Salt mixture has the same spectrum of activity as the dimethosulfate; s.c. injection of the mixture results in formation of a depot from which drug is slowly released; it can also become enclosed in a fibrous capsule or abscess resulting in loss of efficacy (observed chiefly in horses); protective activity may last about 2–3 months depending
Quinapyramine chloride (unstable thick suspension, must be shaken during use) (pig, s.c., behind the ear) °1961	*Trypacide Prosalt (Merial)	
	*Antrycide Prosalt (Alkaline Chemical Corp., India; Bella Trading Khartoum, Sudan)	
	*Noroquine Prosal (Norbrook)	
	*Quintrycide Prosalt (Gharda) (usually used as a 16,7 % aqueous solution)	

On severity of tsetse fly challenge; unexpected acute toxicity (see dimethosulfate), and signs of a delayed toxicity can infrequently occur about 14 days after treatment; signs are loss of condition, weakness, collapse, and death as a result of severe kidney and liver damage; drug is selectively localized in these organs; **quinapyramine chloride** is not commercially available (special order necessary); it has been used prophylactically in pigs; *T. c. simiae* infections in growing pigs can be protected by the chloride, given 50 mg/kg at 3-month intervals; pigs and cattle are remarkably tolerant to the drug; its “depot” effect is due to an “egg-like” deposit from which drug is slowly released giving protection for 3 months in low tsetse fly challenge; target of action of quinapyramine is protein synthesis; it seems to act by displaying Mg ions and polyamines from cytoplasmic ribosomes; there is a similar type of kinetoplast DNA condensation as in diminazene, and an extensive loss of ribosomes

Phenanthridine derivatives (phenanthridinium compounds)

Homidium bromide (soluble in warm water) (1; cattle, deeply i.m.; small ruminants, pigs, horse, i.v.) °1952	Therapeutic use * Ethidium (Laprovect) (2.5 % aqueous solution)	Both salts have a somewhat higher selective effect on <i>T. v. vivax</i> infections in cattle than they have against <i>T. c. congolense</i> ; <i>T. b. brucei</i> is less susceptible; homidium can be used for treating <i>T. v. vivax</i> and <i>T. c. congolense</i> infections in horses and dogs; its limited protective activity in cattle depends on severity of challenge and may last
Homidium chloride (soluble in cold water) (1; cattle, deeply i.m.; small ruminants, pigs, horse, i.v.) °1955	* Novidium (2.5 % aqueous solution); is as active as the bromide) (Merial) Homidium does not cross bloodbrain barrier and is not active against secondary CNS stages of <i>T. b. brucei</i>	

3–5 weeks; mass treatment with homidium resulted in appearance of resistant *T. c. congolense* strains in East and West Africa; homidium-resistant trypanosomes can be controlled by diminazene or isometamidium (enhanced doses); homidium is generally well tolerated at recommended dose and also at higher dose levels (no systemic toxicity); drug may be irritant at site of injection; deep i.m. injection effectively reduces local irritations; severe reactions may occur in horses after i.m. injection whereas i.v. injection seems to be well tolerated (paraveneous injection can lead to severe damage of jugular vein); homidium may be used for prophylactic treatment of slaughter cattle if tsetse fly challenge is moderate and cattle are trekked over not too long distances; it interferes with nucleic acid synthesis by intercalative DNA binding; interaction with DNA depends on length and nature of linking chain causing unwinding and extension; drug binds well to kinetoplast DNA older drugs of this series are **phenidium** chloride and **dimidium** bromide (precursor of homidium), which cause a high incidence of delayed toxicity (marked liver damage) and severe local reaction at injection site; they were replaced by better tolerated homidium

(continued)

Trypanocidal Drugs, Animals, Table 1 (continued)

Chemical group, nonproprietary name (approx. dose, mg/kg body weight, parenteral route) other information	*Brand name (manufacturer, company); other information; ^c first practical (commercial) use of drug	Characteristics (chemotherapeutic effects, adverse effects, miscellaneous comments)
Aromatic diamidines		
Diminazene aceturate (3.5, cattle, sheep, horses, i.m.) ^c 1955	Therapeutic use ^c * Berenil (Intervet) * Ganaseg and others	Is highly effective against <i>Babesia</i> spp. (► Babesiocidal Drugs , Table 1), <i>T. c. congolense</i> , and <i>T. v. vivax</i> , but less active against <i>T. b. brucei</i> and <i>T. b. evansi</i> infections (5–10 mg/kg); drug shows no activity against <i>T. c. simiae</i> ; it seems to have a wide therapeutic index in cattle: subcutaneous doses up to 21 mg/kg were reported to be tolerated in cattle without serious side effects; as ‘sanative’ drug it is used alternately with isometamidium, which
In case of resistant trypanosomes dose can be raised up to 8 mg/kg b.w. but total single dose should not exceed 4 g per animal	(7 % aqueous solution) 1 g of granules contains 445 mg diminazene aceturate and 555 mg phenyldimethyl pyrazolone	
Diminazene does not cross blood-brain barrier and is not active against secondary CNS stages of <i>T. b. evansi</i> and <i>T. b. brucei</i>	(*Antipyrin, an analgesic acting as solvent mediator); withdrawal time before slaughter: 21 days	
Does not cause mutual cross-resistance; its relative ‘rapid’ excretion was believed to reduce risk of parasites becoming resistant (see Pharmacokinetics of Trypanocides and Chemical Residues in Edible Tissues and Milk); trypanosomes resistant to other drugs (except quinapyramine) are commonly susceptible to diminazene; routine and mass treatment may lead to development of diminazene-resistant <i>T. v. vivax</i> and <i>T. c. congolense</i> strains; as a rule, diminazene-resistant strains are		
Susceptible to isometamidium; local reactions can occur in cattle (slight swelling after s.c. injection) and in horses (skin may slough off after s.c. injection, abscess formation after i.m. injection); severe systemic reactions may be evident in equines after higher than recommended doses; camels seem to be most sensitive to diminazene; treating <i>T. b. evansi</i> infections, severe toxic reactions and death can occur at 3.5 and 7 mg/kg, respectively; unexpected side effects (hypotensive, hypoglycemic, and neurotoxic effects: tremor, nystagmus, ataxia, convulsions, vomiting) have been observed in dogs at the recommended dose; for that reason diminazene should only be used in dogs and camels by or under the immediate supervision of the veterinarian; besides its trypanocidal and babesiacidal action, Beremil may exert some anti-inflammatory (antihistaminic) effect; diminazene and pentamidine (► Trypanocidal Drugs, Man , see Pharmacokinetics of Trypanocides and Chemical Residues in Edible Tissues and Milk and ► Chemotherapy/Withdrawal Time of Drugs in Target Animals); diminazene interferes with nucleic acid synthesis; and bind to DNA in vitro (particularly well to kinetoplast DNA) by a non-intercalative mechanism; drug blocks DNA and RNA synthesis (see Search for New Drugs)		
Isometamidium chloride (0.25–0.5, cattle, sheep goats deeply i.m.) (1, dog, buffalo)	Therapeutic use *Samorin (Merial) * Trypamidium (Merial) (1 % aqueous solution)	Metamidium was itself a mixture of two isomers; subsequently the much more soluble, red, highly active isomer was isolated for field trials and named isometamidium; it is a synthetic hybrid like <i>pyrithidium</i> (discontinued) consisting of diazotized p-aminobenzamidine moiety of diminazene molecule linked into 7-position with homidium chloride;
^c 1958, launched in 1961	*Veridium (CEVA, Sanofi Santé Nutrition Animal France)	
	Isometamidium does not cross blood-brain barrier and is not active against secondary CNS stages of <i>T. b. evansi</i>	
Drug is highly active against <i>T. v. vivax</i> infections in ruminants and horses as well as against <i>T. c. congolense</i> infections in ruminants, horses, and dogs; it is less active against <i>T. b. brucei</i> and <i>T. b. evansi</i> infections in horses, ruminants, camels, and dogs; location of the latter <i>Trypanosoma</i> spp. in tissues and body cavities makes them less susceptible to drug action, and treatment with suramin or quinapyramine is therefore suggested; trypanosomes resistant to the drug are usually susceptible to diminazene; acceptable daily intake (ADI, cf. ► Chemotherapy/Withdrawal Time of Drugs in Target Animals) of isometamidium for humans is 6 mg (total intake); maximum residue limit (MRCL) suggested for meat, fat, and milk is 0.1 mg/kg, for liver 0.5 mg/kg, and kidney 1 mg/kg resulting in a withdrawal time of at least 30 days (excluded injection site) for recommended dose		
Isometamidium chloride (0.5–1, deeply i.m., cattle; s.c. injection in	Prophylactic use *brand names see under therapeutic use	Isometamidium provides extended protection at higher doses,

(continued)

Trypanocidal Drugs, Animals, Table 1 (continued)

Chemical group, nonproprietary name (approx. dose, mg/kg body weight, parenteral route) other information	*Brand name (manufacturer, company); other information; ^c first practical (commercial) use of drug	Characteristics (chemotherapeutic effects, adverse effects, miscellaneous comments)
dewlap of cattle may avoid muscle necrosis) (0.5, i.v. 1 % glucose solution over 30 min horses and camels)		2–4 months depending on tsetse fly challenge; medium tsetse fly challenge may require 0.5 mg/kg, heavy challenge 1 mg/kg every 2 months; recommended dose is
Usually well tolerated by cattle; however, i.m. injection can cause severe local reactions like extensive fibrosis at injection site (muscle of neck); i.v. injection in horses and camels may avoid local reaction but may cause systemic toxicity (salivation, tachycardia, profuse diarrhoea, hindleg weakness, collapse due to histamine release); drug can reversibly block neuromuscular transmission and stimulation in cholinergic receptors; extensive accumulation of drug occurs in liver and kidney		
Melaminophenyl arsenicals		
Melarsamine HCl ^c 1989	Therapeutic use ^a Cymelarsen (Merial)	Effective against trypanosomes of the <i>T. brucei</i> group (<i>T. b. evansi</i> , <i>T. equiperdum</i> in camels, buffalo,
Goats and pigs); it was found to be effective against diminazene-resistant <i>T. b. brucei</i> , and <i>T. b. evansi</i> , it is at least 2–2.5 times more effective than Mel W; it is suggested that trivalent cationic arsenicals interact with trypanothion to form the stable adduct Mel T; arsenical agents may be frequently associated with serious side effects (e.g., agent induced encephalopathy)		

Doses listed in this table refer to information from manufacturer and literature or websites on the subject
Data given in this table have no claim to full information

trypanosomiasis = ► [sleeping sickness](#) of man). The relapse due to the appearance of trypanosome populations from privileged sites, such as the cerebrospinal fluid and/or intercellular tissue spaces (parasites from the latter site may also be the cause of relapse in *T. c. congolense* infections). Commonly used drugs, such as **diminazene**, **isometamidium** and **homidium** do not have the ability to cross the blood-brain barrier or produce constant trypanocidal concentrations in body cavity fluids and intercellular tissues that kill trypanosomes. Relapse in chronic *T. b. brucei* infections is evident when chemotherapy was started too late. This is of considerable interest because drug sensitivity changes as the infection progresses. Complete cure is usually achieved when drugs are given in the early stage of infection. In late-stage *T. b. brucei* infections with CNS involvement treatment with non-arsenic drugs gives rise to an apparent cure since parasites disappear from the circulation but, after a period of weeks, they reestablish themselves in the circulation. The natural immunity of humans to the cattle pathogen *T. b. brucei*, but not to the morphological indistinguishable human pathogens *T. b. rhodesiense*

and *T. b. gambiense*, is probably a result of the selective killing of this species by normal human serum containing trypanolytic factors. Unlike in animal trypanosomiasis, the most prominent symptoms of sleeping sickness may result from the marked damage to the CNS in late-stage *T. b. gambiense* (and *T. b. rhodesiense*) infections. **Melarsoprol** and related arsenicals e.g., melarsamine (Table 1), (known for their high systemic toxicity (Trypanocidal Drugs, Man/Drugs Acting on African Trypanosomiasis (Sleeping Sickness) of Humans), are able to cross the blood-brain barrier. A long-term model of African trypanosomiasis in mice producing meningoencephalitis astrocytosis and neurological disorders can be used to understand the pathogenesis of human African trypanosomiasis from initial infection to advanced stages and to evaluate drug efficacy in the late stage of disease. Trypanocides may also be suitable tools in diagnosis of chronic (subpatent) *T. c. congolense* infections in cattle. For this purpose drugs are applied intravenously before and in combination with the indirect fluorescent antibody test. Rapid flushing of cryptic trypanosomes from the microcirculation may

lead to increase of jugular parasite concentrations within 6–10 min of the administration of diminazene, pentamidine, or homidium chloride. However, diamidines given by the intravenous route are liable to give rise to hypotension and other severe, alarming reactions, some of which are due to histamine release.

Current Control Measures

Measures currently used to control trypanosomiasis are diagnosis and treatment, ► [chemoprophylaxis](#), tsetse fly control or eradication of tsetse flies, and the utilization of so-called trypanotolerant breeds. However, this most challenging task in Africa is complicated and hampered by several specific factors. The number of tsetse flies (and thus the occurrence of disease) fluctuates greatly over periods of several years and makes assessment of the actual risk to which livestock are exposed difficult. In addition, control of trypanosomiasis is hindered considerably by the fact that African trypanosomes are able to establish ► [chronic infections](#) in their mammalian hosts because of their highly developed system of ► [antigenic variation](#). Individual members of the parasite population change the composition of their ► [surface coat](#) so that variations in the composition of these variant surface glycoproteins (VSGs) allow the parasite to escape the host's immune system. Thus fluctuating parasitemias produced by *T. brucei* are associated not only with the phenomena of variable antigen type (► [VAT](#)) but certainly also the potential for regulation of trypanosome growth by environmental factors such as epidermal growth factor (EGF), transferrin and low-density lipoprotein. This makes effective immunoprophylaxis unlikely.

In areas with low tsetse fly density the method of choice for controlling African trypanosomiasis seems to be the eradication of the vector. For the time being the spraying of insecticides dominates in tsetse fly eradication. In regions with very low levels of infestation, e.g., by riverine tsetse species (*Glossina palpalis* group, e.g., *G. palpalis*, *G. fuscipes*), trypanosomiasis can be controlled by surveillance and treatment only. Nevertheless,

flies of the savanna (and thicket) group (*G. morsitans* group, e.g., *G. morsitans*, *G. pallidipes*, *G. austeni*) may give rise to severe trypanosomiasis in susceptible stock even if their numbers are low. In these areas commercial cattle ranching may be possible under chemoprophylactic protection. However, tsetse fly density and thus contact between cattle and vector must be reduced by additional spraying of insecticides with residual effects (e.g., synthetic pyrethroids) and by setting up impregnated traps and screens. In areas with medium tsetse fly density the further exploration and logical exploitation of trypanotolerant cattle, including crossbreeding trials with European breeds to increase milk and meat productivity of indigenous trypanotolerant cattle, may offer a realistic alternative to not yet available vaccination. At least in areas with high tsetse fly density even trypanotolerant animals may not survive unless they are treated prophylactically against trypanosomiasis. The control of the disease in fully susceptible stock even under chemoprophylaxis seems to be impossible in regions heavily infected with tsetse.

Tsetse flies can detect odors by means of receptors on their antennae. Experience with insect pheromones was used to identify the chemical components of the ox odor, which might attract tsetse flies and led to the discovery of 1-octen-3-ol. It proved highly attractive to flies of the savanna (*G. pallidipes* and *G. m. morsitans*). Thus live bait (e.g., cattle treated with insecticides: spot-on, pour-on), fly traps, and screens impregnated with “essence of ox” and pyrethroid insecticides (e.g., deltamethrin, or cyfluthrin), and sophisticated ground spraying technology may markedly reduce tsetse infestation in limited areas of riverine woodland or transitional forest-savanna zones. Traps baited with acetone and 1-octen-3-ol have been used in Zimbabwe, Zambia and Malawi to detect the presence and distribution of tsetse flies. It has been shown that **isometamidium** is capable of eliminating the insect vector form of *T. v. vivax*. This experimental finding may be of potential significance in the control of trypanosomiasis in the field, particularly in the operation of the sterile insect technique (e.g., in Nigeria).

Effects of infections on vector survival are of interest for the evolution of parasite-vector interactions since trypanosome transmission depends strongly on vector survival and the frequency of genetic factors controlling vector susceptibility depending on the fitness of infected vectors. In several species of tsetse flies, males from natural populations, and from laboratory-bred colonies, are more likely to develop mature trypanosome infections than females.

Today, there is neither a breakthrough in ► [biological control](#) of tsetse flies nor are there promising solutions for a vaccine against African trypanosomes.

Trypanotolerance of Indigenous African Breeds

The term “trypanotolerance” means reduced susceptibility to trypanosomiasis and denotes an inherited biological property allowing animals to live, breed, grow and survive in a naturally infected environment without exhibiting clinical signs of trypanosomiasis after harboring pathogenic trypanosomes.

In regions where eradication of the vector is not possible with present methods, genetic improvement of trypanotolerant breeds should be attempted. Attention has recently focused on genetic resistance and various selection programs are being discussed to select trypanotolerant animals. Such programs could involve selection of trypanotolerant animals under natural challenge or selection of marker traits (e.g., aspects of the immune response). Selection could also act on polymorphic loci that may affect trypanotolerance, and may be closely linked to genes acting upon tolerance via marker loci. Trypanotolerance is found not only in cattle (all dwarf semiachondroplastic West and Central African types) but also in sheep, goats, and in some rare pony types, such as the Kotokoli of the Ivory Coast. The N'Dama (Hamitic Longhorn of the *Bos taurus* type as well as those breeds of the West African Shorthorn) is a West African breed (e.g., Gambian cattle) noted for its small size and its trypanotolerance. This humpless

breed responds very well to improved management and can attain levels of productivity comparable to that of many African beef breeds of the *Bos indicus* type, such as the West African Zebu, the Orma Boran, the Ankole, or the Afrikander. In addition the N'Dama can maintain reasonable production levels under conditions of poor management, climate, nutrition and high tsetse fly densities. Trypanotolerant breeds of Zebu, sheep and goats may also exist in East Africa. Field studies on two types of large East African Zebu (*Bos indicus*) Boran cattle on a beef ranch in Kenya have demonstrated that a boran type bred by the Orma tribe had a superior response to tsetse fly challenge compared to an improved Boran when introduced to a new locality. Superior resistance to tsetse fly challenge was evident by lower trypanosome infection rate, and when this was untreated, by lower anemia and decreased mortality.

Drug Interactions Associated with Induction of Immunity

Following the successful feeding of tsetse flies infected with *T. c. congolense*, cattle develop local reactions of delayed onset (commonly called a ► [chancere](#)) that persist for several days. The proliferation of the parasite in the hosts skin prior to its passage into the bloodstream via draining lymphatics plays an important role in the induction of immunity, as it is only after regression of the chancre that cattle are immune to tsetse-transmitted homologous challenge. Attempts to induce skin reactions by intradermal injection of bloodstream forms of *T. c. congolense* have failed. Thus, the induction of immunity to trypanosomes may be adversely affected if trypanocidal drugs are given prior to regression of the chancre. In an area of medium tsetse fly challenge it was found that the degree of immunity was greatest in cattle in which infections were established and clinical disease could develop before treatment. Conversely, no immunity developed in cattle treated immediately trypanosomes were seen in the peripheral blood and prior to any evident clinical signs. Induction of immunity to

T. c. congolense in rabbits by infection and treatment with **homidium chloride** may also be adversely affected if animals are infected concurrently with antigenically different stocks of trypanosomes. There was no marked cellular proliferation in the skin at the sites of secondary infection bites following feeding of a single *G. morsitans*; a chancre failed to develop. Possibly the impaired response was due to drug action preventing trypanosomes from developing extravascularly.

On the other hand, the apparent duration of drug protection has been thought to be influenced by protective immunity, which may develop as a result of interactions between insect vector, host, trypanosome population, and drug. These interactive effects may lead to “non-sterile immunity” or “tolerance” in cattle following drug administration and trypanosome challenge. The role of immune responses has been investigated in **isometamidium** treated Boran cattle under single or repeated challenge with *T. c. congolense* infected tsetse flies. Six months after treatment two-thirds of the cattle were resistant to challenge, irrespective of whether animals had received single or multiple challenge. The animals had no detectable skin reactions at the site of deposition of metacyclic trypanosomes and produced no trypanosome-specific antibodies, indicating that drug residues effectively inhibited trypanosome multiplication in the skin and thus subsequent parasitemia. It was concluded that immunological priming of the host had not occurred, and that the protection achieved was not related to the development of immune responses by the host enhancing the length and potency of protection afforded by isometamidium. These findings indicate that development of immunity is not necessary for successful maintenance of cattle in tsetse fly areas provided close control of drug regimes is maintained. The results may also indicate that it is essential to allow multiplication of parasites prior to drug treatment to induce immunity in the host.

Induction of non-specific host defense (e.g., macrophage functional activity) by immunomodulators was demonstrated in 1979 by Murray et al. *Bacillus Calmette-Guérin* (BCG) and *Corynebacterium parvum* were found to enhance the

immune response to *T. c. congolense* infections in susceptible A/J mice and more resistant C57B1/6J mice, both showing reduced parasitemias and increased survival times. This effect could not be transferred from treated to untreated mice of the identical strain by spleen cells or serum. It is not yet clear by which mechanisms immunomodulators influence the course of infection. The development of effective, immunostimulants may provide attractive, complementary tools for combating trypanosomiasis and should be considered as an additional approach to the complex undertaking of a screening program for new trypanocidal drugs and breeding programs for trypanotolerant livestock.

Search for New Drugs

For animal trypanosomiasis no new drugs of any kind have appeared in the field since the introduction of isometamidium in 1961. Nevertheless, aromatic diamidines continue to provide new compounds of high intrinsic activity. Among these, several compounds are highly active on *T. c. congolense* and *T. v. vivax*, while others show a high activity on trypanosomes of the subgenus *Trypanozoon*. Unfortunately, resistance to one trypanocidal diamidine appears to confer resistance to all diamidines, and diminazene-resistant trypanosomes have been shown to be resistant to **DAPI** (4',6-diamidino-2-phenylindole) and other **diamidines** synthesized by Dann and his colleagues. Aromatic diamidines (e.g., pentamidine, diminazene) not only inhibit the growth of protozoans but also of bacteria, fungi and tumor cells, generally at concentrations below those found to be active on the host. DAPI forms fluorescent complexes with double-stranded DNA and is now used for the fluorescent staining of prokaryotic and eukaryotic cells. The drug seems to interact with A-T-rich regions of DNA and thereby to suppress the DNA-directed RNA and DNA polymerases. Several trypanocides (quinapyramine, pentamidine, diminazene aceturate, and isometamidium) and a babesiacidal drug (imidocarb) have been investigated in an activated DNA-directed DNA

synthesis assay system catalyzed by *T. b. brucei* DNA polymerases, murine thymus DNA polymerase alpha, and Rauscher murine leukemia virus reverse transcriptase. From the results obtained it was suggested that trypanosomal DNA polymerases are not the selective target of drugs as they showed a similar dose dependent inhibition to other DNA polymerases of eukaryotic cells. Stimulation of reverse transcriptase activity was observed in the presence of quinapyramine and imidocarb but this could be negated by the presence of spermine in the reaction mixture. As part of studies on N-oxidative biotransformation of amidines, potential metabolites of pentamidine have been synthesized. Although several **amidoximes** of pentamidine and diminazene proved highly active against various African trypanosomes in mice, their potency was inferior to that of the parent compounds. Several compounds of a series of **aryl bisbenzimidazoles** have shown excellent activity against diminazene-resistant *T. c. congolense*, *T. v. vivax*, and *T. b. evansi* strains. Unfortunately this series caused delayed toxicity in calves, including serious liver and kidney damage.

Several antitumor antibiotics have revealed unsuspected high activity against trypanosomes in vitro, particularly DNA and RNA synthesis inhibitors such as 5-chloro-puromycin. **Daunorubicin**, an anthracycline antibiotic intercalating with DNA, which is one of the most potent trypanocidal agents in vitro, has proved totally inactive against *T. b. rhodesiense* in infected mice. Limitations of efficacy and problems with toxicity impose severe limitations on the usefulness of antitumor drugs as potential leads to new trypanocides in humans and animals. The antifungal nucleoside antibiotic **sinefungin**, which strongly inhibits S-adenosyl-methionine dependent transmethylation reactions, has a marked effect on African trypanosomes in mice when administered intraperitoneally. Goats infected with *T. c. congolense* and treated with intramuscular doses of 10 or 20 mg/kg b.w. showed relapse of infection; higher doses (up to 50 mg/kg b.w.) were toxic and caused death. Among a series of novel **purine derivatives** (phosphonyl-methoxyalkylpurines and

▶ **pyrimidines**) with antiviral activity against a broad spectrum of DNA viruses some of them showed potential activity in vivo against *T. b. brucei* at dosages that were below those toxic for mice. **Ketoconazole** and related **azole derivatives** with high activity against *T. cruzi* infections in mice have proved ineffective against *T. b. brucei* in mice. Among a series of **phthalanilides** and related compounds, **BW 458 C** was the most effective in curing short-term and long-term *T. b. brucei* infections in mice. Cure rates greater than 90 % were achieved with the drug at 10 or 25 mg/kg body weight. None of several compounds of a series of **suramin analogues** was more active than suramin against ▶ **macrofilariae** of *Dipetalonema viteae* and various ▶ *Trypanosoma* spp. Inhibition of lipid metabolism in the trypanosomes may be central to the therapeutic effects of the garlic extract containing **diallyl-disulfide** (DAD). DAD is known to have a lipid-regulatory effect and a sulfur-rich compound that readily undergoes ionic interaction with SH being a vital component of coenzyme A. The latter is required in growing cells for the provision of activated acetate molecules, which are then channelled into lipid synthesis and other vital cellular processes.

Salicylhydroxamic acid (SHAM), a substituted aromatic hydroxamic acid, inhibits aerobic energy production (L-glycerol-3-phosphate oxidase system) in trypomastigote stages; it can clear temporarily bloodstream infections of *T. b. brucei* in rats if administered concomitantly with glycerol. In practice, only one far from ideal drug, **melarsoprol** (Mel B) is available to treat late-stage sleeping sickness. Calcium (Ca) has a synergistic effect on this trypanocide and has been shown to be more critical in its action than SHAM + glycerol. These data may be important in the clinical management of sleeping sickness. If total Ca is reduced in a patient it is possible that supportive therapy to restore Ca concentrations could improve the therapy, especially in late-stage Gambian infections.

The reason that potent chelators are trypanocidal but not toxic to mice may relate to acute competition for Fe between the host's Fe-binding proteins like transferrins and ferritin

and the parasite's Fe requirement. Several chelators such as caffeic acid, cuproine, and other commercially available chelators, which had shown heme sparing or inhibition of growth of *Crithidia fasciculata* in vitro were active against *T. b. rhodesiense* in mice after high doses only. Divalent cation chelators such as ethylenediamine tetraacetate (EDTA) or the calcium-specific chelator ethyleneglycol tetraacetate (EGTA) can abolish the synergistic action of heparinized rat blood with SHAM +glycerol. Transferrin may also function as a drug carrier in African trypanosomes in such a manner that complexes of transferrin with isometamidium (Samorin) are targeted directly with high specificity into the lysosome system of *T. c. congolense*.

DL- α -difluoromethylornithine (DMFO = **eflornithine**) is a selective and irreversible inhibitor of ornithine decarboxylase and a key enzyme in polyamine biosynthesis in *T. b. brucei*. The substituted amino acid was shown to have activity against CNS *T. b. brucei* infections in rodents and is the only "new" drug to be developed for the treatment of sleeping sickness in humans. It has proved to be an effective treatment for late stage infections of *T. b. gambiense* in humans [Trypanocidal Drugs, Man/Drugs Acting on African Trypanosomiasis (Sleeping Sickness) of Humans].

There are various areas considered as leads in research relevant to the development of potential new agents for African trypanosomiasis and targets for chemotherapeutic attacks such as, glycolytic enzymes (non-oxidative branch of pentose phosphate pathway = PPP), antigenic variation, and trypanothione metabolism in trypanosomes. Oxidative branch of PPP might be an alternative lead for new drugs. It maintains a pool of NADPH (reduced form of nicotinamide adenine dinucleotide phosphate required for synthesis of fatty acids via phosphogluconate pathway) that serves to protect against oxidant stress and which generates carbohydrate intermediates used in nucleotide and other biosynthetic pathways. Thus 6-phosphogluconate dehydrogenase (6PGDH) in *T. b. brucei* may be a potential target for chemotherapy because in other eukaryotic organisms the deletion of the gene encoding 6PGDH is lethal.

The gene encoding *T. b. brucei* 6PGDH has been cloned, and the enzyme purified and crystallized. Suramin inhibits 6PGDH, and trivalent aromatic arsenoxides inactivate the enzyme with marked potency. Considerable attention has been devoted also to topoisomerases of kinetoplastid organisms. This group of enzymes could be another valuable drug target for new trypanocides. Topoisomerases, which mediate topological changes in DNA, are essential for nucleic acid biosynthesis and for cell survival. Topoisomerase II activity has been purified from *Leishmania donovani*, *T. cruzi* ([► Trypanocidal Drugs, Man](#)) and *T. equiperdum*, and topoisomerase II genes have been cloned also from *T. b. brucei* and *T. cruzi*. Studies with purified topoisomerases indicate that the enzymes from kinetoplastids generally exhibit the expected inhibitor sensitivities. Thus activity is reduced by intercalators acting by deforming the DNA substrate, minor groove binders (compounds that bind in the minor groove of the DNA helix) and compounds that compete for binding at the enzyme's ATP site (e.g., novobiocin, coumermycin). Agents that specifically inhibit type II enzymes by trapping the enzyme on its DNA substrate, forming a "cleavable complex," are the fluoroquinolones and etoposide. Thus, antibacterial fluoroquinolones were shown to exhibit marked activity in vivo against *Leishmania donovani*. Some classical trypanocides such as DNA-binding agents (diminazene and pentamidine: minor groove binders) and intercalators (e.g., ethidium bromide) are well known for their ability to generate dyskinoplastic trypanosomes, which retain mitochondrial membranes but lack detectable kDNA. Selective inhibition of mitochondrial topoisomerase II may be an explanation for the propensity of these drugs to induce dyskinoplastic cells. Because kDNA is not essential for the survival of bloodstream form of African trypanosomes, nuclear rather than mitochondrial topoisomerases should be the preferred target for drug search. Differences in parasite and mammalian topoisomerases may provide the basis for selective toxicity of new trypanocidal compounds. On the other hand, kinetoplasts can be an obligatory target for antitrypanosomal drug action if these organelles are important for

successful subsequent cycling into the insect vectors. There must be some mechanism to assure that an organism does not replicate the nucleus and divide until or unless it has replicated its ► [kinetoplast](#). Drug targeting of kinetoplasts, then, could interfere with cell replication by preempting this regulatory mechanism. Thus identification of regulatory mechanism generating dyskinetoplastic resistance in trypanosomes could possibly provide a basis for new therapeutic approaches. Also molecular biological investigations, as well as inducible gene expression systems (e.g., the tetracycline-responsive repressor of *Escherichia coli*, TetR) in trypanosomes, could suggest potential targets for chemotherapy and pathogenicity.

Drug Combinations with Synergic Effects

For cattle treatment only a few drugs have been developed, and these are involved in resistance problems today. Under such conditions (such as in cancer chemotherapy) exploration of combinations might be an alternative strategy. Therefore, the possibilities of trypanocidal synergic effects of known drugs have been extensively examined in vitro and in vivo using monomorphic laboratory strains of *T. b. rhodesiense*. Only suramin + tryparsamide, suramin + puromycin, suramin + diminazene, and 9-deazainosine + DL- α -difluoromethylornithine (cf. also Search for New Drugs) have been shown statistically significant synergy. Another example of a successful combination therapy is the suppression of chronic *T. b. brucei* infections in mice (CNS involvement) by diminazene diacetate or suramin, each combined with a substituted 5-nitroimidazole (e.g., fexinidazole or MK 436). None of these drugs administered singly caused 100 % permanent cure. Only fexinidazole (Hoe 239) was able to cure a high percentage of the mice when given repeatedly at relatively high dose levels of 250 mg/kg. In several experimental studies fexinidazole has also been found to exhibit a strong effect against *T. cruzi*, *T. vaginalis* and *E. histolytica* in vivo.

Chemoprophylaxis of Cattle Trypanosomiasis

Although there are different ways of combating cattle trypanosomiasis, each of the control methods in use at present has serious limitations. Because of the major economic importance of trypanosomiasis in cattle the great majority of control measures have been aimed primarily at the protection of these animals by the use of suitable trypanocidal drugs. In the absence of a suitable vaccine, chemotherapy and chemoprophylaxis are the most important tactics, which are available as part of any strategy of trypanosomiasis control. They are still considered to be the most effective measures for trypanosomiasis control.

Drugs used for the treatment and ► [prophylaxis](#) of animal trypanosomiasis center on a small number (Table 1). They can be characterized on the basis of their ionization at blood pH as cationic or anionic drugs. Cationic drugs are quaternary ammonium trypanocides (quinapyramine, homidium, isometamidium), and aromatic diamidines (diminazene and pentamidine). The only anionic drug currently in use is presented by suramin. It is a sulfated naphthylamine derivative that readily binds to plasma proteins; it is still widely used in the treatment of equine trypanosomiasis.

The risk of infection to which cattle are exposed is closely related to the density and the species of tsetse fly present. The incidence of tsetse flies thus chiefly determines the frequency of treatment, which is in most regions regulated by the government. The nomadic habits of the major cattle-owning peoples have given rise to the widespread use of trypanocidal drugs and, in general, treatment of individual animals is not practiced. Several authors pointed out that rationale for treating cattle trypanosomiasis is entirely different from that for treating sleeping sickness, for the following reasons. (1) Trypanosomes are very much more common, so that any animal, which becomes infected by tsetse flies, is liable to be infected. Therefore treatment of individuals (or even herds) has no general sanitary significance. (2) Drugs are often given prophylactically

to cattle on their way to slaughter in Africa. Cattle are usually moved over long distances to provide meat in urban areas, and prophylactic drugs are administered so that animals can pass through the “fly belt.” Prophylactic treatment is particularly afflicted with problems concerning variations in the length of protection resulting from varying field situations and the rate of drug elimination from the body (preslaughter withdrawal time). The duration of chemoprophylaxis thus not only depends on the degree of tsetse fly challenge but also on the timing of treatment in relation to occurrence of infection. Insufficient drug protection may result if infection by tsetse flies occurs too early in the trek, and cattle may then succumb to infection before reaching their destination.

The period of effectiveness of prophylactic drugs thus varies with ► [environmental conditions](#), the tsetse fly challenge and activity of the treated animal as well as actual concentration of the active drug (there is the risk of producing a too long-lasting subcurative concentration in blood and tissues). Thus, the period of protection may be considerably reduced particularly during strenuous activity, especially when trade cattle pass through a fly belt in the course of their journey.

Drug Complexes with Enhanced Prophylactic Activity

The prophylactic action of drugs has been prolonged by preparing complexes of **suramin** (anionic drug) with cationic/basic drugs, thereby reducing systemic toxicity of the drugs. Although a **homidium-suramin complex** gave extended protection (6–12 months), it caused unacceptably severe reactions at injection sites. A **quinapyramin-suramin complex** proved active at a single dose of 50 mg/kg body weight in protecting adult pigs and piglets for at least 6 and 3 months, respectively. However such long acting drugs often cause rapid development of drug resistant trypanosomes. Encapsulation of drugs, either in polymers or in artificial phospholipid membranes (liposomes) has been known for a long time. Preparing a complex of isometamidium with the well-defined polyanion

dextran, thereby reducing its toxicity, could enhance the duration of protection produced by the drug. Entrapping homidium bromide in bovine carrier erythrocytes has caused slow release of the drug. However, the various shortcomings of such preparations, like drug quality problems (standardization), marked drug residues (possibly posing a human health hazard) and severe reactions at sites of injection, have hindered the further preclinical development of such preparations. Recently, more promising results were obtained using different types of subcutaneously implanted slow release devices (SRD) containing polycaprolactone/homidium bromide SRD or more readily biodegradable poly (D, L-lactide) or poly (D, L-lactide-co-glycolide) SRD containing either isometamidium chloride or homidium bromide for intramuscular administration. As a result local toxicity was minimized and prophylactic effects in comparison with the parent compounds were markedly prolonged. When breakthrough isolates derived from SRD-treated animals (rabbits) were compared with the original *T. congolense* strain, such isolates showed some loss of sensitivity to homidium only.

Drug Tolerance in the Field and Assays to Assess Intrinsic Trypanocidal Activity

The conditions under which ‘man made drug tolerance’ develops in the field are derived basically from under-dosing due to incorrect estimation of body weight; this is difficult to avoid when mass treatment is involved. A high incidence of trypanosomiasis in conjunction with the irregular use of prophylactic and therapeutic drugs also favors the emergence of drug-resistant trypanosomes. Thus, drug-resistant parasites may emerge in any situation where prophylaxis and therapy are inadequate for the degree of tsetse fly challenge. This may be the case particularly in regions of high tsetse fly challenge. The misuse of drugs leads consequently first to “individual” resistance and then to “area” resistance. Generally, prophylactic drugs induce resistance more rapidly in trypanosomes than do “therapeutic” drugs. The

latter drugs reach trypanocidal plasma levels relatively quickly and may be more rapidly metabolized and excreted from organisms than “prophylactic” drugs. In areas with a high incidence of tsetse flies, subcurative drug levels may already exist towards the end of the protection period, and this is the case particularly after using drugs for prophylaxis. Treatment must therefore be repeated to restore trypanocidal plasma concentrations.

The phenomenon of “natural (intrinsic) drug tolerance,” i.e., variation in drug sensitivity that is not dependent on previous exposure to the drug concerned, has been demonstrated in *T. v. vivax* and *T. c. congolense*. Thus, West African *T. v. vivax* strains seem to be more susceptible to homidium than are East African *T. c. congolense* strains. By contrast, *T. c. congolense* strains appear to be more susceptible to diminazene than are *T. v. vivax* strains. It is likely that the initial appearance of homidium-resistant *T. c. congolense* strains and diminazene-resistant *T. v. vivax* strains can be connected directly with the varying intrinsic sensitivity of these species of a given drug. Some of this variation in drug sensitivity may also be the result of persistent cross-resistance induced by quinapyramine, which was extensively used for therapeutic and chemoprophylactic treatment before homidium became the drug of choice. Differences in drug sensitivity of stocks of the subgenus *Trypanozoon* have also been reported. In an in vivo assay designed to minimize the influence of host-parasite interactions using X-irradiated trypanosomes, it was demonstrated that isoenzymically defined West African *T. b. brucei* stocks were not as sensitive to pentamidine and diminazene as typical East African stocks. This test sought to measure the intrinsic sensitivity of a trypanosome population by reducing the influence of extrinsic determinants of drug sensitivity, in particular trypanosome “penetration” of tissues inaccessible to drugs and host antibody-mediated relapses of parasitemia.

Problems involved in using inappropriate in vivo models for testing drug sensitivity may be overcome by culturing trypanosomes in vitro, allowing precise detection of intrinsic sensitivity

of all stages in the life cycle of trypanosomes. The use of simple in vitro assays using feeder layer-free in vitro systems may help to obtain rapid information on the susceptibility of isolated trypanosome strains to the drug concerned. However, based upon the ability of these assays to predict potential drug efficacy in vivo, not all fresh isolates or clones of trypanosomes can be grown in feeder layer free systems. Thus, a combined mammalian feeder layer-trypanosome culture system may make it possible to determine different effects of a compound on host cells (general toxicity) versus parasites (selective toxicity). Calcium antagonists of several chemical classes including verapamil, cyproheptidine, desipramine and chlorpromazine, alone and in combination with various trypanocidal drugs (suramin, diminazene and others), were unable to reverse resistance in *T. evansi* to any of the trypanocides tested in vitro. These results are in contrast with those occurring in *T. cruzi*, ► *Plasmodium*, ► *Leishmania* and cancer cells, in which calcium antagonists have successfully reversed resistance.

Use of Drugs in the Field to Control Cattle Trypanosomiasis

Current limitations on drug efficacy are due to the occurrence of trypanosomes showing multiple drug tolerance to several drugs with close chemical relationship. This has been true also for a *T. v. vivax* strains first reported from Kenya in 1985. Thus a “cocktail” of 11 *T. v. vivax* isolates has proved resistant to all drugs on the market, e.g., to isometamidium chloride (2 mg/kg b.w.), diminazene aceturate (3.5 mg/kg b.w.), homidium chloride (2 mg/kg b.w.), and quinapyramine sulfate (5 mg/kg b.w.). This finding appears to have implications of considerable importance to East African cattle producers. The ability of *T. v. vivax* to cause a hemorrhagic syndrome has also been discussed. Hemorrhages apparently do not occur in all cases and not in all stages of the disease. This form of trypanosomiasis can be acute or peracute and is responsible for severe losses in unprotected stock.

The main problem in chemotherapy and chemoprophylaxis is to control the widespread cross-resistance in trypanosomes to the few drugs on the market (Table 1). Resistance to a drug, which has developed as a result of previous exposure of trypanosomes to a different drug of the same series or to a drug of an unrelated series can only be effectively controlled by using drugs that do not induce resistance to each other. If this is the case, then they can be used alternately when resistance to either drug appears in the field. In the early 1960s significant knowledge of cross-resistance patterns was obtained from studies of large numbers of cattle maintained under controlled field condition in East Africa. Insufficient response of trypanosomes to certain prophylactic and curative drugs at recommended doses led to the strategic use of “sanative” pairs of drugs in the field. Such drug pairs include homidium/diminazene and isometamidium/diminazene, which show no cross-resistance although quinapyramine-resistant trypanosomes confer resistance to each of these drugs. Moderate side-resistance may also be present between homidium, and isometamidium, which belong to the same chemical class of phenanthridines. Increased doses of isometamidium (1–2 mg/kg b.w.) may, however, control resistance to homidium.

In curative field programs homidium may be used until evidence of resistance appears. It should then be replaced by diminazene, which generally controls infections in cattle reinfected with homidium-resistant parasites. Homidium may be used again after a year or so. Isometamidium and diminazene may be used alternately in prophylactic field programs. However, the appearance of drug-tolerant strains is believed to be inevitable in these programs, particularly in high-risk areas where isometamidium chloride is used at the standard dose of 1 mg/kg b.w. every 3 months. This dose may protect cattle against trypanosomiasis for 6–12 weeks if tsetse fly challenge is not too high. Higher dose levels can cause local reactions, a problem, which is common to all prophylactic drugs currently used (for comments see Table 1).

Control of the disease has been maintained when quarterly prophylactic injections with

isometamidium were supplemented by block treatment with diminazene at regular intervals, i.e., every 6 months, 1 month prior to routine treatment with isometamidium. “Sanative” diminazene will not control the situation if the challenge becomes too high as a result of increasing rates of reinfection with resistant trypanosomes. *T. v. vivax* and *T. c. congolense* strains, which survive isometamidium doses of 1 mg/kg b.w. and are cross-resistant to homidium can be controlled, however, by repeated administration of diminazene acetate at a dose of 7 mg/kg b.w.

Field observations on the **stability of drug-resistance** in trypanosomes undergoing cyclical transmission are contradictory. Some observations suggest that drug resistance is stable and transmissible, while other investigators have assumed that drug-resistance in a trypanosome population is transient in the absence of drug pressure and infected cattle. In a series of experiments drug tolerance to curative doses of trypanocides was shown to be of stable nature, while *T. v. vivax* and *T. c. congolense* were transmitted through tsetse and cattle. However, it was assumed, that in the field competition between resistant and sensitive parasites in the trypanosome population might lead to an advantage for sensitive forms resulting in a gradual disappearance of drug-resistant parasites.

Pharmacokinetics of Trypanocides and Chemical Residues in Edible Tissues and Milk

There has been increasing public health concern about the consumption of trypanocidal drug residues in foods. A survey conducted recently in central Kenya has shown significant quantities of trypanocides in cattle meat from various slaughterhouses. Previously, the phenanthridines (Table 1) **isometamidium** (for MRLs see Table 1) and quinapyramine have been believed generally to maintain trypanocidal blood concentrations for longer periods than diminazene. This led to the assumption that storage in and release from deep compartment are due to a process different from that occurring with diminazene. Thus, diminazene

has been found to have only a limited prophylactic effect, and patent parasitemia has often been detected 2 weeks after treatment. This indicates that diminazene may be rapidly removed from bloodstream if given as the readily water-soluble aceturate. In contrast, the virtually water-insoluble diminazene dihydrochloride (or embonate) yielded in rats a fairly long protection period of 56–70 days at subcutaneous doses of 1×16.5 and 1×33 mg/kg b.w. against a high challenge of *T. b. rhodesiense* and *T. b. gambiense*. It was also demonstrated that diminazene diaceturate was “rapidly” removed from the plasma in mice whereas its tissue concentration remained relatively high for several weeks. In rhesus monkey (*Macaca mulatta*) the elimination of diminazene aceturate (single intramuscular dose of 20 mg/kg b.w.) occurred in two phases with half-lives of 2.1–2.7 h and 15.5–23.3 h; the protection period against a high challenge of *T. b. rhodesiense* was 21 days. Similar biphasic elimination of the drug was observed in rabbits after intramuscular injection of 3.5 mg/kg b.w. 7 days after treatment 40–50 % of the dose had been excreted in the urine and 8–20 % in the feces; the highest diminazene residues were found in the liver and corresponded to 35–50 % of the dose given.

Pharmacokinetic studies in cattle provided further evidence for the validity of a two-compartment model in the case of diminazene; there were a biphasic profile and two phases of distribution. Pharmacokinetic properties of **diminazene diaceturate** [bisphenyl- $U^{14}C$] (3.5 mg/kg b.w. i.m.) were investigated in healthy calves. Levels of radioactivity were determined in the blood, plasma, urine, feces, and edible tissues. There was a rapid onset of absorption, which led to high blood, and plasma levels (4.6 nEq/ml). The decrease in concentration followed a biphasic process with half-lives of 2 and 188 h; 20 days after administration 72.2 % and 10.3 % of the dose had been excreted in the urine and feces, respectively. The main product in urine was unchanged diminazene. Radioactivity could be detected in blood and plasma for up to 20 days after administration. Distribution studies

revealed low concentrations in edible tissues, particularly in skeletal muscle and fat. From these results it was concluded that diminazene is not as rapidly and entirely metabolized (or biotransformed) in the body as suggested previously. Following the results a preslaughter withdrawal time of 21 days for all edible tissues (also liver) was recommended for cattle. A similar long preslaughter withdrawal period (14–20 days) was estimated for sheep after a single intramuscular dose of diminazene 3.5 mg/kg. Drug concentrations were determined in plasma and equilibrium dialysis and high-performance liquid chromatography. As expected, dairy goats that had received two successive intramuscular doses of diminazene aceturate 2 and 3.5 mg/kg b.w. showed somewhat different pharmacokinetics from those that received a single injection. The estimated preslaughter withdrawal period was between 28 and 35 days. Dairy cows repeatedly infected with different strains of *T. congolense* and treated with different dose of radiolabelled diminazene aceturate have been investigated for dependence of drug residue levels in milk. Results of this study indicate that the degree of parasitemia (anemia) affects the distribution, disposition, and elimination of diminazene. At 3.5 mg/kg b.w. 0.4 % of the dose was excreted in milk after 21 days, while 0.54 % of the 7 mg/kg b.w. dose was excreted during the same time. On the basis of data of half-lives for the second phase (elimination phase) milk from treated animals should not be consumed for at least 3 weeks posttreatment. In rabbits treated with a single intramuscular dose of [^{14}C] **homidium** bromide 1 or 10 mg/kg b.w. blood and tissue levels reached a maximum within 1 h then fell rapidly. After 4 days 80–90 % of the radioactivity injected had been excreted, 33 % in the urine and 66 % in the feces. In view of the rapid rate of drug excretion it was assumed that the time and level of infection relative to the time of drug administration might markedly affect the protective action of ethidium. Some doubt must therefore remain about the value of this drug for the prophylactic treatment of slaughter cattle as recommended previously.

Changes in the Field of Animal Trypanosomiasis Over the Past 40 Years

Based on a review of the literature with special reference to control of animal trypanosomiasis in Africa, the conclusion was that each of the control methods in use has serious limitations. This appears to be true also for the present situation. Today and in the past, the effectiveness of chemoprophylaxis and chemotherapy has been reduced markedly by the widespread development of drug resistance. The enormous cost involved in research on and development of new drugs, which industry has to consider, have meant that very little research on potential trypanocides has been done. Thus, 30 years ago some pharmaceutical companies were still involved in research on the chemotherapy of trypanosomiasis, despite the financial considerations of the relatively small market and uncertain financial returns. Economic and ecological constraints on trypanosomiasis control are still evident, and the high cost involved in a continuing program of eradication of tsetse flies, or even of isolated tsetse-belts, is often beyond the reach of individual countries. Furthermore, tsetse fly clearance remains an unreliable control measure when continued surveillance is not guaranteed, and tsetse fly eradication will not necessarily result in the eradication of trypanosomiasis since *T. v. vivax* and *T. b. evansi* can cause infections without cyclical transmission and can be spread mechanically by biting dipterans. On the other hand, attempts to eradicate tsetse flies by chemical control, e.g., by massive aerial insecticide spraying, are always associated with considerable adverse effects on environment.

Biological and genetic control methods are still at an early stage of development (as 30 years ago) and control of trypanosomiasis by immunological tools will only be achievable on a long-term basis. It seems likely that research into the response of trypanotolerant cattle will be of special value although host-parasite relationships and thus, trypanotolerance are still poorly understood. All these limitations would be less important if the present control measures were used in an

integrated control program; the importance of international cooperation in combating trypanosomiasis should be stressed. However, the problems encountered in the organization of control programs differ greatly according to whether the method of control is directed against the parasite or the vector tsetse fly. Campaigns directed against the vector are much more a matter of straightforward organization, logistics, and cost (e.g., considerations of the economic return from development after tsetse fly eradication) than are those which involve the attack of infections of the vertebrate host using curative or prophylactic drugs. Perhaps the most valuable use of trypanocidal drugs is in the development of cattle rearing and production in areas where tsetse fly eradication cannot be achieved in the near future. In such areas, conditions can gradually be created under which operations against tsetse flies may be undertaken. Thus, attention must be drawn to one of the chief remaining constraints on the improvement and multiplication of trypanotolerant livestock, i.e., the relatively low reproductive performances of certain cattle breeds under traditional management systems.

Trypanocidal Drugs, Man

See Table 1 (pp. 1500, 1501).

Drugs Acting on African Trypanosomiasis (Sleeping Sickness) of Humans

In humans, *Trypanosoma brucei gambiense* and *T. b. rhodesiense* cause ► [African trypanosomiasis](#) (► [Sleeping Sickness](#)); the disease is transmitted by the bite of infected tsetse flies (► [Glossina](#) spp.). These two subspecies are morphologically indistinguishable but differ in their pathogenicity and thus disease pattern. In animals, *T. b. brucei* and other ► [Trypanosoma](#) spp. cause the disease ‘nagana’ (► [Trypanocidal Drugs, Animals](#)). *T. b.*

Trypanocidal Drugs, Man, Table 1 Drugs used against trypanosome infection of humans

African trypanosomiasis (sleeping sickness) epidemic/endemic in a belt across central Africa south of the Sahara Desert and transmitted by the bite of infected tsetse flies (*Glossina* spp.); in tsetse, trypomastigotes transform into epimastigotes, which divide during a complicated migration in the fly and then transform into metacyclic trypomastigotes infective for humans and reservoir animals (*T. b. rhodesiense*); **chemotherapy** in patients with CNS involvement (sleeping sickness) is generally problematic because of many undesired side effects caused by arsenical drugs such as melarsoprol; corticosteroids have been used to prevent reactive arsenical encephalopathy (encephalopathic syndrome), which can be fatal (3–10 %); an increase of resistance to the drug has been observed in several foci particularly in central Africa (~20 % of patients with *T. b. gambiense* fail to response to melarsoprol); the type of treatment depends on the stage of the disease; drugs used in the hemolymphatic or first stage of the disease are less toxic, easier to administer and more effective than arsenicals; drugs that can cross the blood–brain barrier to reach the parasite (second stage treatment) are quite toxic and complicated to administer; **four drugs** are registered for the treatment of sleeping sickness and provided free charge to endemic countries through a WHO private partnership with Sanofi-Aventis, Specia (pentamidine; also Fujisawa, melarsoprol and eflornithine) and Bayer AG (suramin); for treatment of *T. b. gambiense*, pentamidine and suramin have equal efficacy but pentamidine is better tolerated

Parasite; disease distribution	Stages affected (location comments)	Chemical class other information	Nonproprietary name adult/*pediatric dosage, routes	Toxic effects other information
<i>T. brucei gambiense</i> hemolymphatic (first) stage (West and central Africa, probably only human reservoir)	Trypomastigote Gambian disease (chronic with low parasitemias; incubation time: months to years)	Aromatic diamidines (does not pass blood-brain barrier); pentamidine (Pentam, others) was discovered in 1949	Pentamidine isethionate drug of choice regimen for adults and children: 4 mg/kg/day i.m. × 10 day <i>alternative</i> : suramin : adult/*pediatric dosages: cf. <i>T. brucei rhodesiense</i> ↓	Contraindication: diabetes; drug can induce pancreatitis, hypo- or hyperglycemia, sharp fall in blood pressure after i.v. injection; renal dysfunction is reversible; abortion and peripheral neuritis (rare)
<i>T. brucei rhodesiense</i> hemolymphatic (first) stage (East Africa, zoonotic infection, reservoir hosts: antelope, hartebeest, cattle, lion, hyena and others)	Trypomastigote Rhodesian form (acute with high parasitemias; incubation time: days to weeks)	Sulfated naphthylamines (anionic urea compound) does not pass blood-brain barrier; high protein binding activity; suramin (Germanin, others) was discovered in 1921	Suramin (drug of choice) regimen for adults children: *20 mg/kg on days 1, 3, 7, 14 and 21; 100–200 mg (test dose) i.v., then 1 g i.v. on days 1, 3, 7, 14 and 21	Side effects may be shock, loss of consciousness (rare), urticaria, colic, heavy proteinuria, severe toxic (degenerative) effects on kidney (withdrawal of drug!), peripheral neuropathy as paresthesia, hypoesthesia, agranulocytosis and hemolytic anemia (rare)
<i>T. brucei gambiense</i> Late disease with CNS involvement (West and central Africa, probably only human reservoir)	Trypomastigote Gambian disease (chronic with low parasitemias; incubation time: months to years; parasites cross blood-brain barrier and may be found in cerebrospinal fluid causing severe inflammation reactions)	Melaminophenyl arsenicals (trivalent cationic compound) melarsoprol (Mel-B) was discovered in 1949 (it pass blood-brain barrier) substituted amino acid : eflornithine was registered in 1990; it is only effective against <i>T. brucei gambiense</i> ; the regimen is strict and difficult to apply	Melarsoprol regimen for adults and children: 2.2 mg/kg/day i.v. × 10 day; pre-treatment with <i>suramin</i> in debilitated patients; in frail patients increase the dose progressively (initial dose is as little as 18 mg) eflornithine regimen for adults and children: 400 mg/kg/day i.v. in 4 doses × 14 days; it is an alternative to Mel-B treatment	Most serious side effect of melarsoprol is reactive encephalopathy (cf. text of table ↑, hospital supervision is necessary), other adverse effects may be: fever, joint pain, renal damage, myocarditis, peripheral neuropathy, gastrointestinal disturbance, hypersensitivity or hypertension; eflornithine is less toxic than Mel-B and highly effective against <i>T. brucei gambiense</i> ; side effects see ↓

(continued)

Trypanocidal Drugs, Man, Table 1 (continued)

<i>T. brucei rhodesiense</i> Late disease with CNS involvement (East Africa, zoonotic infection, reservoir hosts: antelope, hartebeest cattle, lion, hyena and others)	Trypomastigote Rhodesian form (acute with high parasitemias; incubation time: days to weeks; parasites cross blood-brain barrier and may be found in cerebrospinal fluid causing severe inflammation reactions)	Melaminophenyl arsenicals (trivalent cationic compound) for other information see text ↑	Melarsoprol regimen for adults and children: 2–3.6 mg/kg/day i.v. × 3; after 7 days 3.6 mg/kg/day i.v. × 3 days; repeat again after 7 days; in frail patients: begin with 18 mg and increase the dose progressively; <i>suramin</i> pre-treatment in debilitated patients	Eflornithine is not effective against <i>T. brucei rhodesiense</i> infections; in patients with Gambian disease it may cause frequent anemia and leukopenia, occasionally thrombocytopenia, seizure, diarrhea, hair loss (rare)
---	---	---	--	--

American trypanosomiasis (Chagas' disease): zoonosis with an extensive mammalian reservoir (armadillos and opossums, some domestic animals and humans) is endemic in Central and South America, being found only in the American Hemisphere. *T. cruzi* may be transmitted to humans in two ways, either by blood-sucking infected reduviid, or directly by transfusion of infected blood (iatrogenic transmission); the vector bugs infest poor housing and thatched roofs; acute phase of disease is seen in children with and without acute clinical manifestations (all patients must be treated with a trypanocidal drug); lesions of chronic phase irreversibly affects internal organs such as heart, esophagus, colon and peripheral nervous system (treatment is indicated in recent chronic infection of children); chronic cases with established pathology appear to be unable to benefit from long-term treatment (~60–90 days: hospitalization or careful monitoring may be needed); *T. rangeli* differs from *T. cruzi* by longer and better developed undulating membrane, and small subterminal kinetoplast; *T. rangeli* appears to be non-pathogenic to man; only (T) forms in blood of humans, resemble *T. cruzi*

<i>Trypanosoma cruzi</i>	Trypomastigotes (=T), amastigotes (=A)	2-nitroimidazoles (drug of choice in Brazil because of fewer drug-tolerant strains than elsewhere), mode of action may be interactions of its metabolites with DNA	Benznidazole	Side effects common: immediate and frequent hypersensitivity reactions (rashes in 30 % of treated patients), bone marrow suppression, psychic and GI disturbances, peripheral polyneuritis, leucopenia, agranulocytosis (rare); side effects can lead to interruption of treatment
Precautions	(T) in blood and (A) in: cardiac muscle, smooth muscle of gut, skeletal muscle		Rochagan (Roche Brazil) (drug of choice, 5–7 mg/kg/day in 2 divided doses orally × 30–90 day *≤12 years: 10 mg/kg/day orally in 2 doses × 30–90 day	
Neither benznidazole nor nifurtimox should be given to pregnant women; in patients with illnesses associated with Chagas disease potential risk of severe adverse effects should be considered carefully dividing (A) forms produce pseudocysts; daughter (A) transform back to (T); these enter blood and may then reinvade various muscular tissue		Nitrofurantoin derivatives (no longer readily available) addition of γ -interferon for 20 days may shortened acute phase of disease (RE McCabe et al., J Infect Dis 163: 912, 1991) mode of action may be production of free oxygen radicals enhancing oxidative stress on (T) + (A)	Nifurtimox Lampit (Bayer) (alternative drug, 8–10 mg/kg/day orally in 3–4 doses × 90–120 day *1–10 years: 15–20 mg/kg/day orally in 4 doses × 90 day *11–16 years: 12.5–15 mg/kg/day orally in 4 divided doses × 90 day)	Side effects common (50 %): gastrointestinal complaints as anorexia, nausea, vomiting; vertigo insomnia, headache, peripheral neuritis, myalgia, arthralgia; neurological reactions: excitability; rare: convulsion, rashes, pulmonary infiltrates and pleural effusion; side effects can lead to interruption of treatment

Dosages and other information refer to data from The Medical Letter, Drugs for Parasitic Infections, 46 (1189), August 16, 2004, literature, and WHO websites (publications/medicines, and others)

Data cited in the table have no claim to full information

Abbreviations: *d* days, *mg/kg* mg/kg body weight, *i.m.* intramuscularly, *i.v.* intravenously

gambiense infection is widespread in West and Central Africa whereas *T. b. rhodesiense* is restricted to the East and East Central areas with some overlaps between both species. In 37 countries of sub-Saharan Africa, 22 of which are among the least developed countries in the world, more than 55 million people are at risk of African trypanosomiasis.

Differences in host specificity are due to a nonimmune killing factor (trypanosome lytic factor = TLF) in human serum causing lysis of *T. b. brucei* in vitro and in vivo. African sleeping sickness trypanosomes are resistant to this factor which is long known and may support chemotherapy. In the bloodstream of infected humans the trypanosomes grow and multiply extracellularly as long slender (LS) forms. After several divisions they transform into first intermediate (I) forms and then nondividing short stumpy (SS) forms, which are infective for tsetse. The latter possess a functional mitochondrion. **Eflornithine** (DMFO, cf. ► [Trypanocidal Drugs, Animals](#), Table 1), interfere with the division process of LS forms and reduce hemolymphatic ► [trypomastigotes](#) and those in the central nervous system (CNS) (for more information see below and Table 1).

West African trypanosomiasis produced by *T. b. gambiense* is chronic in nature lasting up to 4 years. In the absence of chemotherapy, patients with Gambian infection become progressively more wasted and comatose. Involvement of (CNS) disorders, damage of the heart, and other organs generate the classical picture of sleeping sickness. Disease caused by *T. b. rhodesiense* is more acute and may last rarely longer than 9 months. Without treatment, death often occurs from toxic manifestations before CNS changes are evident. Because Rhodesian form is a zoonotic disease (reservoir animals) treatment of infected humans has less effect on incidence of infection in humans. In contrast, control of Gambian form and hence treatment of infected individuals relies mainly on surveillance of human population and direct field diagnosis by mobile teams. In general, cure rates are higher when infected individuals are treated in the early phase of the disease.

Only four drugs are available which may be used for the treatment of African trypanosomiasis

(► [Trypanocidal Drugs, Animals/Search for New Drugs](#)). **Suramin** and **pentamidine**, which were discovered in the first two or three decades of last century, are still used for clearing blood and the hemolymphatic system from trypanosomes in the early phase of the disease. The trivalent arsenical **melarsoprol** (Mel B) and eflornithine, which cross the blood-brain barrier, are used for the treatment of later CNS stages of the infection. Melarsoprol is derived from melarsen and its phenylarsenoxide with the melaminyl moiety in the *p*-position. It requires parenteral administration as other standard trypanocides. It may be extremely effective but highly toxic in all advanced CNS cases and need hospitalization and considerable care in its use (► [Trypanocidal Drugs, Animals](#)). Melarsoprol exhibits a rapid lethal effect on trypanosomes in the CNS causing the so-called Herxheimer-Jarisch type of reactive encephalopathy in up to 10 % of the treated patients with a mortality rate of 3–10 %. Recent data on clinical pharmacokinetics led to an alternative regimen of melarsoprol, which could reduce its toxicity. The only “new” drug developed for the treatment of sleeping sickness is **eflornithine** (DL- α -difluoromethylornithine = DMFO, Ornidyl, cf. [Trypanocidal Drugs, Animals/Search for New Drugs](#)). In *T. b. brucei* ► [polyamines](#) are synthesized from ornithine, and DMFO is a highly inhibitor of ornithine decarboxylase (ODC), which catalyzes the decarboxylation of ornithine to yield putrescine and then spermidine. Polyamines play an important role in cell division and differentiation of eukariotic cells. Depletion of putrescine (and thus spermidine) leads to inhibition of the transformation of the LS form to the SS form and therefore to inhibition of trypanosome growth. When administered in drinking water, DMFO selectively blocks multiplication of the parasites and eliminates the infection. It was shown to have activity against CNS *T. b. brucei* infections in rodents, and has proved to be an effective treatment for late stage infections of *T. b. gambiense* in humans, even in arsenical-refractory CNS patients. Although eflornithine is highly active against Gambian trypanosomiasis its use may be limited (available via WHO). Clinical trials with the drug have

been performed and are going on to evaluate its trypanocidal efficacy and systemic toxicity in patients with Gambian sleeping sickness. Dosage regimen, which had successfully been used, was 400 mg/kg/day intravenously in four divided doses for 14 days, followed by oral treatment with 300 mg/kg/day for 3–4 weeks. The drug may have some “minor” drawbacks such as variable activity against *T. b. rhodesiense* infections and the need for high parenteral doses in late cases which makes treatment management questionable. A combination of DMFO and suramin has been on trial for the treatment of CNS involved Rhodesian infections.

The current regimen for the treatment of early *T. b. rhodesiense* and *T. b. gambiense* infections is **suramin** or pentamidine. In late stage Rhodesian infections, patients are treated first with suramin to clear the blood and lymph from parasites and then with multiple injections of **melarsoprol**. **Pentamidine** isethionate is the drug of choice for the treatment of early (primary) *T. b. gambiense* infection. It may also be used in late (secondary) stage patients with CNS involvement to eliminate hemolymphatic trypanosomes prior to administration of melarsoprol (for route and dosage cf. see Table 1). In addition, it had been used in prevention and control projects (FAO/WHO initiative initiated in 1993, or PAAT = program against African trypanosomiasis) in epidemic/endemic regions of Angola, Cameroon, Central African Republic, Congo, Gabon, Equatorial Guinea, Uganda, Sudan, Chad and Zaire.

Retrospective long-term study with the diamidine, **diminazene** aceturate (Berenil, Intervet), by follow-up of 99 human patients with early-stage disease of sleeping sickness showed that there was satisfactory efficacy after the parenteral route, and side effects were no more serious than those produced by suramin. However, the drug exhibits reduced activity after oral administration because its extensive hydrolysis in stomach results in two metabolites: one is 4-amidinophenyl-diazonium chloride, which exerts distinct trypanocidal activity, the other is 4-aminobenzamidinium dihydrochloride, which proves ineffective against *T. b. brucei*.

Drug Acting on American Trypanosomiasis (Chagas Disease) of Humans

Trypanosoma cruzi is the causative agent of Chagas’ disease (American Trypanosomiasis) and occurs only in the Western Hemisphere from the Central American countries in the North to the Andean countries and Southern Cone countries in the South. Uruguay was certified free of vectorial and transfusional transmission of Chagas disease in 1997 (WHO, CTD homepage January 1999). The disease affects 16–18 million people and some 100 million, i.e., about 25 % of the population of Latin America is at risk of acquiring Chagas disease. Rural migration to urban areas changed the traditional epidemiological pattern of Chagas disease; it became an urban disease, as unscreened blood transfusion created a second way of transmission. *T. cruzi* is primarily an intracellular parasite (amastigote stages) occurring as ► **pseudocysts** in cardiac and smooth muscle cells, glial cells of the brain, and mononuclear phagocytes. However, immediately after the infection of the host by the reduviid bug (various species *Rhodnius*, *Triatoma*, *Panstrongylus*) first trypomastigote stages circulate in the bloodstream. During this early phase of infection, which may last up to 60 days, trypomastigote forms can be detected by direct examination of peripheral blood (by wet smear or after staining) along with the detection of IgM anti-*T. cruzi* antibodies. All patients suffering from acute Chagas disease must be treated since cure rate (checked by parasitological and serological assays) in the acute phase of infection may be 50–60 % only. Positive serological reactions in children 6 months after birth are indicative of congenital transmission and ► **xenodiagnosis** or hemoculture may corroborate the serological finding; specific treatment should be started immediately. Treatment is indicated in recent ► **chronic infections**, especially in all children with positive serological reactions whose infection occurred a few years (<10) ago. Patients (selected cases) with the indeterminate form, slight cardiac form and digestive form may be treated as well. To assure the free passage of the chemotherapeutic drug and its

absorption, symptomatic treatment of dysphagia is recommended in cases with megaesophagus. However, it is not clear whether etiological intervention will stop the progression of the disease in chronic patients. Operational problems should be envisaged in the majority of chronic infections because long-term treatment demands thorough and proper follow-up of adverse effects caused by chemotherapy. Reactivation of Chagas disease may occur in immunosuppressed patients (e.g., HIV infection, ► [AIDS](#) related infections, or any organ transplantation) but clinical manifestations usually differ from those of the acute phase. For this reason, adequate monitoring of a potential *T. cruzi* infection should be done. In cases where parasitological reactivation is evident, chemotherapy should be envisaged though the risk of severe side effects may increase, or ► [chemoprophylaxis](#) has been suggested for these patients.

Current treatment is based on the nitrofuran, **nifurtimox** (no longer readily available), and the 2-nitroimidazole, **benznidazole**. Both drugs are administered orally for prolonged time (dosage and side effects cf. Table 1). Successful treatment requires either hospitalization or careful monitoring of the patient. There may be marked variation in the drug response of different *T. cruzi* strains. Therefore, in the acute phase of infection, cure rates with both drugs are not total and vary regionally. There is limited or no action of both drugs on the chronic phase of the disease. However chemotherapy is essential in immunocompromised patients showing meningo-encephalitis.

Allopurinol (structural analogue of hypoxanthine), a drug used to decrease the excessive amounts of uric acid in the blood caused by gout and other metabolic disorders, may be a low cost, non-toxic alternative for treatment of *T. cruzi* infection. However, results from clinical trials indicate some doubt of its efficacy. The drug is taken up by the purine salvage pathway and prevents formation of ATP and also interferes with nucleic acid synthesis (► [Leishmania](#) spp. cf. ► [Leishmaniacidal Drugs](#), Table 1).

Sterol biosynthesis inhibitors such as the antifungal azoles, **ketoconazole** and **itraconazole**

and the more recently investigated D0870, the *R* (+) enantiomer of ICI 195,735 continue to be potential chemotherapeutic agents against Chaga's disease, especially at the chronic stage. However, previous studies in humans have failed to corroborate the action of ketoconazole on *T. cruzi* reported from animal models (for information on chemotherapy including regimen and adverse effects of current drugs see Table 1).

For the control of vector-transmitted infection through triatomid ► [bugs](#) (popular names: "vinchuca," "barbeiro," "chipo," and others) the objective is to interrupt transmission of *T. cruzi* by insecticide spraying, insecticidal paints, fumigant canisters, housing improvement and health education in rural and suburban areas. The basic strategy includes house spraying with modern pyrethroids followed by long-term, community-based surveillance designed to report any "residual" infestation that then can be selectively treated. For the control of blood-transmitted infections the goal is to screen all blood donors from endemic countries for *T. cruzi* antibodies (including HIV and hepatitis B). **Gentian violet** (Aksuris, Oxiuran, Viocid) toxic and mutagenic to mammals is still used as a disinfectant against *T. cruzi* in blood samples of potential infected donors. In blood banks of urban areas, transmission of *T. cruzi* by blood transfusion remains a major problem.

Trypanoplasma

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *trypanon* = piercing structure, *plasma* = formed structure.

Trypanoplasma, Fig. 1 Life cycle of *Trypanoplasma* sp. in fish (carp) and vector leech (*Piscicola geometra*). 1 Transformed metacyclic stages with a long free end of the recurrent flagellum (F_2) and a thick surface coat (TH) occur in the blood after inoculation by the leech. 2-4 During binary fission stumpy forms finally appear, whose recurrent flagellum (SF) has a short end. These forms (4) are mainly found in the bloodstream when fish are kept in cold water, and may infect leeches during a blood meal. 5-7 Developmental stages inside the pharynx, esophagus, and upper intestine of the vector have a reduced

surface coat (SS). The slender forms (7, 8) are attached to the intestinal wall. The stumpy forms (7.1-7.4) are seen free inside the blood masses and may recolonize the intestine after each sucking phase. 8 Metacyclic stages with a thicker surface coat (TS) are found in the anterior parts of the intestine and are injected into fish during blood meal of the vector. F_1 free flagellum, F_2 recurrent flagellum, FR long free end of recurrent flagellum, KI kinetoplast, N nucleus, SJ short free end of recurrent flagellum, SS slight surface coat, TS thick surface coat

Classification

Amédée Borrel (1867–1936), French microbiologist.

Genus of ► [Kinetoplastida](#).

Life Cycle

Figure 1.

Disease

► [Trypanoplasmosis of fish](#).

Geographic Distribution/Epidemiology

Worldwide in freshwater and saltwater.

Morphology/Lifecycle

The stages of the species *T. borreli* (rudd), *T. cyprini* of carp, and *T. salmositica* of salmon live in the blood of their hosts are characterized by the presence of two flagella, two kinetoplasts, and an enormously stretched mitochondrion, while only a single nucleus is present. The free ends of the flagella are at least 10 µm long. Their length reaches 15–20 µm, but some species may differ considerably in their shape. There are slender as well as compact forms (Figs. 1), which apparently do not belong to different species, but are differently aged stages. They all live in the bloodstream (infection rates up to 80 %).

Trypanoplasmosis of Fish

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek, *trypanon* = boring system; *plasma* = fluid mass. Latin, *cyprinus* = carp; *salmo* = salmon;

Trypanoplasmosis of Fish, Fig. 1 *Trypanoplasma* sp.; slender (1) and compact (2) stages within the blood of a carp. Note the long free parts of the flagella

Symptoms of Disease

Apathy, reduced feeding, anemia, weight loss, and often death (especially in the case of young fish in ponds/aquaria with high temperatures).

Diagnosis

Microscopical analysis of Giemsa-stained blood smears.

Infection

Bites of leeches (e.g., *Piscicola*) and crustaceans (e.g., so-called carp lice = *Argulus* and related species).

Prophylaxis

In farm ponds practically impossible, however, vaccination trials of salmonids are in test.

Incubation Period

Four to seventeen days.

Prepatent Period

Five to sixty days.

Patency

Months, years.

Treatment

Possible only in aquaria by using Flagello[®] of Fa. Sera, Heinsberg, Germany.

Trypanorhyncha

Within the class Cestoda, besides the Cyclophyllidae, most other orders are fish parasites. Many primitive cestodes such as the Diphyllidae and Tetraphyllidae are marine group of tapeworms and are common parasites in the spiral valve of elasmobranchs. Of these, the order Trypanorhyncha Diesing, 1863 is among the most species-rich. More than 260 valid species have been described, and new species are added every year. They infest the stomach and intestine of sharks and rays (Elasmobranchii) as final hosts. Therefore, they have a cosmopolitan distribution and, in accordance to the species-richness of their final hosts, they belong to the most abundant fish parasites in tropical waters. The larval stages live in various organs of teleost fish and also in marine invertebrates, such as crustaceans, cephalopods, and bivalves. Some larvae have been recorded even from sea turtles, sea snakes, and also from the living fossil *Latimeria chalumnae*.

Trypanorhynchs have complex, indirect life cycles and can be found in all tropic levels of the marine food web. Two main groups of trypanorhynchs can be identified. The mainly ray parasitic eutetrarhynchoids develop non-operculated eggs (oncosphere) with an enclosed embryo that is freed from the eggshell when eaten by a copepod first intermediate host. It develops into the proceroid in the first and into a plerocercus inside invertebrates as second intermediate hosts. For example, *Prochristianella hispida* lives in the spiral valve of dasyatid sting-rays, such as *Dasyatis sayi*, in the Gulf of Mexico, with the number of parasites increasing with the host fish size. Experimental first intermediate hosts were the harpacticoid copepod *Tigriopus*

californicus and *Mesochra* sp., and infective plerocerci were identified in the mud shrimp *Callinectes islagrande*.

The mainly shark parasitic lacistorhynchoids develop operculated eggs that release a free-swimming coracidium following the eggs' release into seawater. A relatively undifferentiated proceroid develops in copepods as first intermediate hosts. Second intermediate hosts are teleosts. A low level of host specificity in many species enables them to successfully infest a wide range of different host species worldwide. Experimental infestation of the leopard shark *Triakis semifasciata* was successful with *Lacistorhynchus dollfusi* from the US Californian coast. The eggs released free-swimming coracidia 5 days following the eggs' release into seawater. They are infective for the harpacticoid copepod *Tigriopus*

californicus. The proceroid within the haemocoel of the copepod is infective to small teleosts, such as the mosquito fish *Gambusia affinis*. In the body cavity or muscle of its teleost host, the plerocercus is protected within a blastocyst and develops the same scolex morphology as typical for the adult worm. A similar life cycle pattern, however, involving different hosts from the various marine habitats, is assumed especially for those trypanorhynchids that live in mainly pelagic or oceanic environments (Figs. 1 and 2, page 1506).

Main distinguishing feature of trypanorhynch cestodes is the characteristic scolex with two or four bothria and a tentacular apparatus for attachment (Fig. 1). Four evaginable tentacles are connected to tentacle sheaths and bulbs that function hydrostatically. They are adorned with numerous hooks that are arranged in highly complex patterns (Fig. 2) and are adapted to the typical attachment site inside the final host. Both, adults and plerocerci have the same armature pattern along the tentacles, enabling exact identification. Reaching an individual body length from millimeter to meter, the whitish colour, high abundance, and ability to infest the musculature of many commercially important fish species make

Trypanorhyncha, Fig. 1 The lacistorhynchoid trypanorhynch cestode *Grillotiella exile* from the tiger shark (*Galeocerdo cuvier*) and the gills of the narrow-barred Spanish mackerel (*Scomberomorus commerson*) as its intermediate host. Scolex with two bothria and armed tentacles (worm length = 0.8 mm). Note the heteromorphous hooks that are arranged in a complex pattern (Photos courtesy of Professor. H. W. Palm, University Düsseldorf)

Trypanorhyncha, Fig. 2 The lacistorhynchoid trypanorhynch cestode *Grillotiella exile* from the tiger shark (*Galeocerdo cuvier*) and the gills of the narrow-barred Spanish mackerel (*Scomberomorus commerson*) as its intermediate host. Tentacular armature of *Grillotiella exile*. Note the heteromorphous hooks that are arranged in a complex pattern (Photos courtesy of Professor. H. W. Palm, University Düsseldorf)

these cestodes an important group for fisheries and the fish processing industry.

^aThe stumpy blood stages are always somewhat shorter (± 10 µm)

^bAccording to its main transmission mechanism it belongs to the Salivaria group

susceptible to the lipase GPIPLC. The procyclic insect stage of the same parasites is covered with another GPI-anchored protein named ► **procyclin**, the ► **GPI anchor** of which differs from that of the ► **VSG** by acylation of the inositol ring that renders it insensitive to GPIPLC.

Minor surface proteins related to ► **VSG** present on trypomastigotes seem to be involved in interacting with host molecules.

On the surface of *Trypanosoma cruzi*, another class of GPI-anchored proteins closely related to higher eukaryote mucins has been described. These highly *O*-glycosylated structures are acceptors of sialic acids for the surface transsialidase, and are involved in ► **host cell invasion** in the trypomastigote stage. These mucins are encoded by several hundreds of genes with hypervariable regions that are differentially expressed among developmental stages, leading to stage-specific mucins on the surface of these parasites.

Host Cell Invasion

T. cruzi has a broad host-range and can infect in vitro a variety of different cell types from a number of species. Trypomastigotes invade both phagocytic cells and cells incapable of phagocytosis. Amastigotes have also been shown to be able to invade both types of cells. It is not yet known whether one or two mechanisms of internalization occur, i.e., phagocytosis and active invasion. Early works have suggested that phagocytosis (or induced phagocytosis) was the mechanism of internalization (► **Apicomplexa**, Fig. 8). More recent studies have shown that the process is an induced internalization in a lysosomal compartment induced by the parasites after recruitment of the host cell ► **lysosomes** in the area of initial cell contact by the parasite. Lysosomes are actually induced to fuse with the plasma membrane of the cell at the site of contact and this leads

Trypanosoma, Fig. 1 Life cycles of *Trypanosoma brucei gambiense* and *T. b. rhodesiense*, causatives of the ► [sleeping sickness](#) diseases in West and East Africa (Fig. 3). 1 Slender trypomastigote bloodstream forms (they also penetrate into the cerebrospinal fluid). These stages are characterized by a mitochondrion with sparse, short, tubular cristae. The slender forms lack a functional Krebs cycle and cytochrome chain. 1.1 According to several authors, ► [amastigotes](#) (i.e., Micromastigotes) are seen 48 h later inside the cells of chorioidea. 1.2 Transformation of amastigotes into sphaeromastigote forms (► [surface coat](#) not investigated), which give rise to slender blood forms. 2 Intermediate ► [trypomastigotes](#) which reproduce by intensive ► [binary fission](#); cristae of mitochondrion lengthen. 3 Stumpy trypomastigote forms have a partially functional Krebs cycle but still lack cytochromes. When these stages are ingested by the tsetse fly (► *Glossina* spp.), they may develop inside this vector. According to results of Jenni (Basel), bloodstream forms are diploid, and sexual processes with mating and DNA recombination occur inside the vector.

4 Trypomastigotes (without surface coat) in the crop of the tsetse fly. A waiting phase of at least 1 h is needed. 5 Transformation to epimastigote (= procyclic) forms in the cardia and midgut of the tsetse fly; these stages develop a smooth surface coat and divide for about 12 days. 6 Epimastigote forms have a mitochondrion with numerous platelike cristae, acting with an active Krebs cycle and the cytochrome chain. Reproduction occurs by constant binary fission. These stages leave the intestine and enter the salivary glands. 7 Metacyclic trypomastigote from the salivary glands, which develops a blood-stage surface coat (DS) and has a mitochondrion with closely packed tubular cristae. This stage is infectious for man and reservoir hosts when injected during the next blood meal of the vector. The whole development in the vector lasts 25–50 days and each tsetse fly remains infected for life (=2–3 months). The minimum infective dose for man is about 300 flagellates. DS developing blood-stage surface coat, F flagellum, KI ► [kinetoplast](#), MI mitochondrion, N nucleus, SC surface coat, SF short flagellum of amastigotes (for further species see Table 1, p. 1507)

Trypanosoma, Fig. 2 Life cycle of *Trypanosoma cruzi*, cause of Chagas' disease in South America (Fig. 4). 1 Amastigotes = micromastigotes reproduce by binary fission inside the ►cytoplasm of different host cell types (RES, heart muscle, nerve, spleen, liver, etc.). Host cells appear as "pseudocysts" when they are completely filled with parasites. 2, 3 Transformation to trypomastigotes (3) via ►epimastigotes (2) and development of a surface coat (*DS*) occurs inside the cell. 4 Trypomastigotes inside the bloodstream after disruption of the host cell. These stages enter other host cells or are ingested by cone-nosed ►bugs during the blood meal. 5 Transformation to epimastigotes inside the midgut of reduviid bugs (*Rhodnius* spp.; *Triatoma* spp., etc.) after blood meal.

These stages are attached to the intestinal wall and reproduce by binary divisions, thus being accumulated in high numbers. 6 Epimastigotes in the hindgut of bugs; they were transformed to metacyclic stages with a specific surface coat. 7 Metacyclic (= infectious) stage (trypomastigote) inside the rectum of bugs. These stages are set free in fecal droplets during blood meal on their hosts. They enter the skin after the blood meal through a bite channel, scratched skin, or via mucous membranes. Inside the mammalian host they penetrate into various cells. *DS* developing surface coat, *F* flagellum, *HC* host cell, *KI* kinetoplast, *MI* mitochondrion, *N* nucleus, *NH* nucleus of the host cell, *SC* surface coat, *SF* short flagellum

to internalization. Parasite-induced signalization is involved, inducing calcium transients in the host cell responsible for lysosome ► [exocytosis](#); this signal is dependent on a parasite cytoplasmic serine protease (prolyl oligopeptidase).

Intracellular trypanosomes are located in a membrane bound parasitophorous vacuole immediately after invasion, but they are rapidly found in the host cell cytoplasm, which suggests that

they are able to leave the vacuolar compartment where they are first found. They develop in the cytoplasm of the host cell (► [Apicomplexa](#), Fig. 8). This escape phenomenon is due to the rise in vacuolar pH due to the lysosomal nature of the vacuole which activates the parasite surface transsialidase that degrades the sialyl moieties of the vacuolar membrane proteins (essentially the lysosomal glycoprotein LGP), allowing a parasite

Trypanosoma brucei evansi

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

G.H. Evans (1835–1935) and David Bruce (1855–1931), Engl. scientists. Hindi: *surra* = Indian term for bad, wicked).

Geographic Distribution/Epidemiology

Northern Africa, India, Southeast Asia, and Central and South America. Main hosts are camels, equids, ruminants, and dogs; since several strains of this species are rather harmless, while others are very pathogenic, the true rates of distribution are difficult to estimate. In any way in many regions, the disease (*surra*) is economically very important. Furthermore human cases have been reported.

Morphology/Life Cycle

The parasites are monomorphic and occur as long, slender trypomastigotes and reach a length of 13–34 μm (Fig. 1). Their flagellum surpasses the anterior end and the kinetoplast (situated at the posterior end) is subterminally situated. Some strains do not show a typical kinetoplast and are thus called dyskinetoplastic. In these cases apparently lower amounts of DNS are included in their mitochondrion. These parasites in the blood of their hosts are transmitted mechanically due to bites of tabanids and *Stomoxys calcitrans*. In addition transmission may also occur in Central and South America during the blood meal of bloodlicking vampire bats. Thus, the life cycle runs acyclic, since in the vectors no reproduction occurs in contrast to *T. brucei brucei*.

Symptoms of Disease (*surra*)

Fever, edemas, anemia, swellings of lymph nodes and spleen, and occasionally also premature/still-birth. The symptoms of disease are milder in case of cattle and small ruminants, while equids and camels get severely sick.

Diagnosis

Microscopic demonstration of parasites in the blood (e.g., after concentration), PCR techniques, and ELISA tests.

Trypanosoma brucei evansi, Fig. 1 Light micrograph of a Giemsa-stained blood smear preparation of *T. brucei evansi* and other *T. brucei* species of cattle. Langform = long form; Kurzform = short form.

Infection

Percutaneous during bites of mechanical vectors (tabanids, bloodsucking flies, vampire bats).

Prepatent Period

1 week.

Prophylaxis

Use of repellents against tabanids and bloodsucking flies.

Patency

Months.

Incubation Period

1 week.

Therapy

Berenil® (5–10 mg/kg body weight i.m.) or phenanthridine derivatives (e.g., Novidium®/Homidium chloride, 1 mg/kg body weight i.m.)

and Samorin[®] (Isometamidium, 0.24–0.5 mg/kg body weight i.m.).

% due to *T. b. rhodesiense* and 98 % due to *T. b. gambiense*.

Trypanosoma brucei Group of Humans

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *trypanon* = boring system; *soma* = body. The species name honors the English scientist David Bruce (1855–1931), who detected these parasites.

Geographic Distribution/Epidemiology

Trypanosoma brucei rhodesiense in East Africa and *T. brucei gambiense* in West Africa. It is believed that due to slave transportation from East Africa to West Africa (to the formerly named Côte d’esclaves), the disease was transported from West Africa also to East Africa. There had been large epidemics around 1900 in Central and East Africa killing millions of inhabitants of, e.g., Belgian Congo or of the English colonies in the region of Lake Victoria. Today there are still several hundred thousand humans infected in West and East Africa. The number is again increasing since actually numerous ethnic/religious local wars prohibit early treatment. Today about 50 million people are endangered and about 10000 seriously infected: 2

Morphology/Life Cycle

The life cycle is diagrammatically depicted in Fig. 1. The agents of disease are longitudinal stretched flagellates, which possess a single flagellum that originates in all stages from the bottom of a flagellar pocket (Figs. 2 and 4). The stages in the blood (called trypomastigotes) are 15–40 µm long, and their single flagellum is anchored at the posterior cell pole. This flagellum is attached at several places to the cell membrane of this stage, thus producing there the aspect of a so-called undulating membrane. At the anterior pole of the so-called trypomastigote stages (Fig. 3a, b) the flagellum becomes free, and by its propeller-like movements the parasite is able to swim forward in the host’s blood. The surface of this stage is covered by a layer of proteins and mucopolysaccharides, which change its composition during each of the repeated longitudinal binary fissions (► VSG). This variation is produced by the alternative activity of up to 1,000 different genes, so that the immune system of the host is unable to eliminate a patent infection. Cell division always starts by doubling the basal apparatus of the flagellum and the so-called ► kinetoplast, which represents a peculiar DNA-rich region of the single mitochondrion close to the basis of the flagellar pocket (Fig. 2). Food uptake occurs by a phagocytosis in the flagellar pocket (Figs. 3 and 6) (physiology of trypanosomes). The nucleus of the cell stages of the trypanosomes is always located in the center of the parasite (Figs. 2, 3, and 6), while the flagella may start at the posterior pole (= trypomastigote stage), before the nucleus (= epimastigote stage, Fig. 5), or at the anterior pole (= the tiny not protruding remnant of a flagellum in the amastigote respectively micromastigote stages). The mitochondrion, which stretches through the whole cell body of all stages (Figs. 1, 2, and 6), has different activities inside the vertebrate host and in the vector (= the blood-sucking flies of the genus ► *Glossina* tsetse flies). The blood

Trypanosoma brucei Group of Humans, Fig. 1 Life cycles of *Trypanosoma brucei gambiense* and *T. b. rhodesiense*, causatives of the ► [sleeping sickness](#) diseases in West and East Africa. **1** Slender trypomastigote bloodstream forms (they also penetrate into the cerebrospinal fluid). These stages are characterized by a mitochondrion with sparse, short tubular cristae. The slender forms lack a functional Krebs cycle and cytochrome chain. **1.1** According to several authors, ► [amastigotes](#) (i.e., micromastigotes) are seen 48 h later inside the cells of chorioidea. **1.2** Transformation of amastigotes into sphaeromastigote forms (► [surface coat](#) not investigated), which give rise to slender blood forms. **2** Intermediate ► [trypomastigotes](#) which reproduce by intensive ► [binary fission](#); cristae of mitochondrion lengthen. **3** Stumpy trypomastigote forms have a partially functional Krebs cycle but still lack cytochromes. When these stages are ingested by the tsetse fly (► [Glossina](#) spp.), they may develop inside this vector. According to results of Jenni (Basel), bloodstream forms are diploid, and sexual processes with mating and DNA recombination occur inside

the vector. **4** Trypomastigotes (without surface coat) in the crop of the tsetse fly. ***Trypanosoma brucei* Group of Humans, Fig. 3** Light micrograph of trypomastigote stages of *T. b. gambiense* (a) and *T. b. rhodesiense* (b)

stages appear in two stages: the slender, long stages (20 - 35 μ m) and the so-called stumpy forms of 15 - 25 μ m (Fig. 1). Only the stumpy forms are able to survive and reproduce in the *Glossina* species, while the slender ones, which

get their energy by anaerobic glycolysis, are apparently able to pass the blood-brain barrier. In the brain they induce (probably after stage conversion to micromastigote stages) the typical symptoms of the trypanosomiasis

(insomnification). *T. b. gambiense* and *T. b. rhodesiense* parasitize besides in humans also in so-called reservoir hosts such as monkeys, dogs, pigs, antilopes (in the case of *T. b. gambiense*) and goats, sheep, cattle, and some species of antilopes in the case of *T. b. rhodesiense*. In contrast to this multihost disease *T. brucei brucei* of cattle and other ruminants (disease: ► [Nagana](#)) never attacks humans.

Symptoms of Disease (Trypanosomiasis, Sleeping Sickness)

1. First stage

- (a) At first **edema** and swellings of the skin (3 - 15 mm) occur at the biting sites of the tsetse flies, which persist for up to 3 weeks

Trypanosoma brucei Group of Humans,
Fig. 4 Scanning electron micrograph of a trypomastigote stage

due to the huge local reproduction of the injected trypomastigote stages. Numerous of these stages can be found in the fluid of the edema.

- (b) **Fevers** up to 39 °C occur from the 2nd to 4th week after the bite, since then the reproduced trypomastigotes start to enter the circulating blood. These fevers persist for 2–3 weeks (depending on how quickly antigens destroy such stages). Repeated parasite reproduction and particles due to their host-derived destruction lead to further fever outbreaks reaching temperatures of up to 41 °C, which were repeated at nonregular intervals. In infections with *T. b. gambiense* the fevers never start with chills, which, however, is a leading sign in *T. b. rhodesiense* infections.
- (c) **Lymph node swellings** (polyadenitis) are found when the parasites start to enter the blood vessels, especially in the case of *T. b. gambiense* infections. These swellings occur along the lateral side of the neck (Winterbottom sign).
2. **Second stage:** In this phase the parasites enter the brain. This starts in *T. b. rhodesiense* about 3 months after the infection but in *T. b. gambiense* only after 9–18 months. This brain penetration initiates the typical symptoms of a progressive meningoencephalitis, which leads without treatment to death. Therefore it is needed to diagnose the occurrence of parasite stages inside the liquor cerebrospinalis, since

Trypanosoma brucei

(d) Trypomastigote in longitudinal section. (e) Trypomastigote in cross-section. (f) Flagellar pocket in cross-section. AR axial rod, AX axoneme, B basal body, DG dense granules, glycosome = place of transformation of glucose to 3-phosphoglycerate, ER endoplasmic reticulum, F flagellum, FP flagellar pocket, FU finger-like channel, GO golgi apparatus, K kinetoplast, L lipid, MI mitochondrion, MT microtubule, N nucleus, NU nucleolus, PM peritrophic membrane, SCO surface coat, glycocalyx, UM cell membrane, V vacuole

their occurrence there requires another treatment. In untreated cases the name-giving symptom of “ongoing sleeping” occurs, which is the final step to death, often combined with myocarditis.

Diagnosis

With respect to the bad prognosis of this disease it is absolutely necessary to verify an infection at the most early date. This can be done by puncture of edemas, by microscopic inspection of the fluid for motile trypomastigote stages, or by examination of Giemsa-stained smear preparations. Since the parasitemia increases and decreases due to the

activity of the human immune system, it is needed to repeat such investigations in cases with negative results. Further easy methods for enrichment of eventually present parasites are the use of the so-called microhematocrit technique and the differential centrifugation. One of the most successful techniques is the ion exchange chromatography (according to Lanham). In the case of a suspected infection with *T. b. rhodesiense* also the injection of 0.5 ml blood of the patient into a rodent laboratory animal will show the parasites there within 3–9 days. Serological methods (IFT, ELISA, CATT) show IgG and IgM antibodies. Unfortunately also false-positive and false-negative results have been reported.

Trypanosoma brucei
Group of Humans,

Fig. 7 Nobel Prize winner (1905) Robert Koch and coworkers on the famous *Trypanosoma* expedition in East Africa during the years 1906/1907

Infection

The infection occurs during bites (i.e., salivarian infection) of both sexes of the blood-sucking tsetse flies of the genus ► *Glossina*. **Attention:** Transmission may also occur during blood transfusions.

Prophylaxis

Use of repellents (e.g., Viticks[®], Deet[®], Autan[®]) in endemic regions of Africa (► [saltidin](#)).

Incubation Period

Within 1–21 days local edema occurs around the bite sites (primary effect). After 3 weeks fever starts. Three months after the infection cerebral dysfunctions occur in *T. b. rhodesiense* and after 9–12 months in the case of a *T. b. gambiense* infection.

Prepatent Period

One to three weeks.

Patency

Maybe years in the case of the (rare) chronic cases.

Therapy

The drug of choice in the **first stage** of *T. b. rhodesiense* is Suramin[®]: test doses: 100 mg due to occasional idiosyncrasia; then 20 mg/kg bodyweight on day 1, 3, 7, 14, and 21. Maximal dose: 5 g. **Attention:** nephrotoxicity may occur. In cases of bad acceptance or resistance: Pentamidin: 4 mg/kg bodyweight daily i.m. or i.v. for 7–10 days (however, efficacy against *T. b. rhodesiense* is not sure!). In the **second stage** of the disease application of melarsoprol (high toxicity) and eflornithin is recommended. The maximum daily dose of **melarsoprol** should not exceed 3.6 mg/kg bodyweight (application for 3–4 days, then interruption for 5–6 days, then 3–4 times repetition of this cycle). **Eflornithin:** Scheme of therapy: for 14 days daily 4 times at 6-h-intervals: 100 mg/kg bodyweight. Priotto et al. (2009) recommend as treatment of *T. b. gambiense* the use of a combination of nifurtimox and eflornithine.

Trypanosoma brucei
Group of Humans,

Fig. 8 Photo of Robert Koch (right) and his wife visiting his famous co-worker Kitasato in Tokyo

Trypanosoma brucei Group of Humans, Fig. 9 The first anti-*Trypanosoma*-product. It was marketed as Bayer 205, later Germanin, Suramin

Attention: Untreated cases end fatal, but also 15 % of treated cases die.

In the times of ► [Robert Koch](#) the toxic arsenic preparation ► [atoxyl](#) was used, which later was replaced by B205 = Germanin = Suramin of our days (Figs. 7, 8 and 9).

Trypanosoma cruzi

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *trypanon* = boring system; *soma* = body. The species name honors the Brazilian scientist Oswaldo Cruz (1872–1917), who offered the physician Carlos ► [Chagas](#) (1879–1934) a laboratory position. During his work in this lab, he detected the life cycle of this parasite.

Geographic Distribution/Epidemiology

This parasite is distributed in several species of raptor bugs in South America, Central America, and Southern and Western United States reaching from Argentina/Chile until California. In these regions around 50–80 million people are infected – living mostly under poor social conditions. Due to recently increasing worldwide migration, the parasite is now also found in numerous humans in Europe and Asia, too. ► [Chagas disease](#) – non-epidemic cases.

Morphology/Life Cycle

Besides humans, many ► [reservoir hosts](#) such as armadillos, opossums, dogs, cats, monkeys, and rodents (all belonging to a so-called ► [sylvatic cycle](#)) may suffer from Chagas' disease. They all become infected by bloodsucking raptor bugs belonging to several genera (e.g., *Triatoma*, ► [Dipetalogaster](#), *Rhodnius*). However, in contrast to the transmission of the agents of the African trypanosomiasis by bites of both sexes of tsetse fly species of the genus *Glossina*, *T. cruzi* stages are included in the feces of the raptor bugs.

Just after bloodsucking the engorged bug excretes a droplet of feces with trypomastigote stages of *T. cruzi* (Fig. 1). These feces are transported by the bug itself or by scratching movements of the blood donor to the biting site, where the parasites thus get the chance to enter easily the host's body. In light micrographs, these stages of *T. cruzi* appear as trypomastigotes being S or C shaped reaching a total length of about 15–20 µm and a width of 1.5 µm (Fig. 2). They enter quickly the hosts at the biting site and later are found inside macrophages and muscle and nerve cells, where they are situated inside the cytoplasm. They change their shape and start reproduction as amastigotes (= micromastigotes), change shape to become epimastigotes, and reach finally again the original structure of trypomastigotes, which are characterized by a long slender shape with a flagellum that starts at the posterior pole of the cell within a flagellar pocket. Finally, the host cells, which are now called pseudocysts (Fig. 3), rupture and set free large numbers of these trypomastigotes. They enter immediately neighboring cells and start again reproduction. Since the host cells become destroyed, many organs (such as the heart) become severely damaged. This constant reproduction and tissue destruction may persist for years and is mostly not noted by the patient, since the intracellular reproduction does not introduce intense immune reactions. If a bug ingests during its blood meal trypomastigote stages, they become attached at the intestinal wall in the midgut and transform during longitudinal binary fissions to epimastigote stages (Fig. 4). After a while they reach the hindgut, where they are transformed into the trypomastigote stage (Fig. 1) and are excreted within the feces during or after sucking acts on the skin of a potential new host.

Symptoms of Disease

The disease due to introduced trypomastigotes is called Chagas' disease or American

Trypanosoma cruzi, Fig. 1 Life cycle of *Trypanosoma cruzi*, cause of Chagas' disease in South America. (1) Amastigotes = micromastigotes reproduced by binary fission inside the ► **cytoplasm** of different host cell types (RES, heart muscle, nerve, spleen, liver, etc.). Host cells appear as "pseudocysts" when they are completely filled with parasites. (2, 3) Transformation to trypomastigotes (3) via ► **epimastigotes** (2) and development of a surface coat (DS) occurs inside the cell. (4) Trypomastigotes inside the bloodstream after disruption of the host cell. These stages enter other host cells or are ingested by cone-nosed ► **bugs** during the blood meal. (5) Transformation to epimastigotes inside the midgut of reduviid bugs (*Rhodnius* spp., *Triatoma* spp., etc.) after blood meal. These stages are

attached to the intestinal wall and reproduced by binary divisions, thus being accumulated in high numbers. (6) Epimastigotes in the hindgut of bugs: they were transformed to metacyclic stages with a specific surface coat. (7) Metacyclic (= infectious) stage (trypomastigote) inside the rectum of bugs. These stages are set free in fecal droplets during blood meal on their hosts. They enter the skin after the blood meal through a bite channel, through scratched skin, or via mucous membranes. Inside the mammalian host they penetrate into various cells. *DS* developing surface coat, *F* flagellum, *HC* host cell, *KI* kinetoplast, *MI* mitochondrion, *N* nucleus, *NH* nucleus of the host cell, *SC* surface coat, *SF* short flagellum

Trypanosoma cruzi,

Fig. 2 Light micrograph of trypomastigote stages of *T. cruzi*

**Trypanosoma cruzi,**

Fig. 3 Transmission electron micrograph of a section through a muscle fiber (= pseudocyst), which is filled with developmental stage of *T. cruzi*

trypanosomiasis, which starts with an **acute phase** being later followed by a **chronic phase**. After entrance in a new host, the trypomastigotes introduce an intense inflammation (called chagoma) at the biting site. In this case this primary symptom occurs mostly in the face region. Strong swellings and reddening of the skin are common as well as swelling of the eye lids and the connective tissues of the eye. The periocular region appears swollen, too. After 1–3-week long incubation period, the distribution of the parasites starts as soon as the local reproduction phase has been finished. The parasites are then distributed in

the host's body via bloodstream leading to fever and swelling of the lymph nodes, followed by hepatosplenomegaly and edemas at legs and in the face. Children may suffer from meningoencephalitis and/or myocarditis, which may lead to death – sometimes already during the acute phase of the disease. Then the symptoms decrease within the next weeks. However, the trypomastigotes are now common in the peripheral blood. These trypomastigote stages are C or S shaped, possess a large kinetoplast, and are characterized by a pointed terminal end (Fig. 4). These stages are clearly different from those of

Trypanosoma cruzi, Fig. 4 Diagrammatic representation of the epidemiologic relations of *Trypanosoma cruzi*. (a) Development in man (Giemsa stain). (1) Metacyclic trypomastigotes reach man in reduviid bug feces (a). (2, 3) Intracellular transformation to amastigote stage in the "pseudocyst" with marked multiplication and development through epimastigote stage into trypomastigotes. (4, 5) Trypomastigote forms from the peripheral blood. (b) Development in the intestine of the reduviid bug vector (*Triatoma* sp.). (6) Freshly sucked up trypanosomes in the process of division. (7) Transformation to the epimastigote form. (8) Metacyclic trypomastigote form from bug feces.

► *T. rangeli*, which are transmitted by the same bugs as those of *T. cruzi*, but are enclosed in the bug's saliva.

During the chronic phase of the disease, which may last for years without significant symptoms (i.e., **intermediate phase**), parasites are only rarely seen in the peripheral blood, so that they are mostly absent in diagnostic blood smears or even after the use of concentration methods. This is due to the fact that the parasites are now mainly concentrated in various cells of the host. The destruction of these cells, especially those in the heart, may introduce a sudden death of the patient. Diagnostic criteria during this phase are severe alterations of the electrocardiogram. The histological damages affect many organs, so that death occurs due to multiple organ deficiency.

Diagnosis

Demonstration of trypomastigotes is possible during the first acute phase when investigating fresh blood or stained blood smears respectively thick droplets. Better results are obtained by differential centrifugation or by the use of the microhematocrit method. This method is very easy and successful when used according to Strout's method.

During the chronic phase the parasites cannot become demonstrated directly. However, in 40–50 % of the cases, the **xenodiagnosis** is successful. Following this method, 40 laboratory-bred (= parasite-free) bugs (3rd/4th nymphal stages) were placed within tiny baskets onto the skin of patients. After 30–60 days their intestinal

←
Trypanosoma cruzi, Fig. 4 (continued) (BB) Coprophagy and cannibalism lead to infection of the young reduviid bugs at the larval stage of development. (c) Development similar to that in man (a) occurs in the parasite reservoir (armadillo, opossum, dog, and other animals). Transmission by reduviid bugs can take place: (1) From man to man $A \rightarrow B \rightarrow A$. (2) From animal to animal (parasite reservoir) $C \rightarrow B \rightarrow C$. (3) From animal to man and vice versa $C \rightarrow B \rightarrow A$. (4) From bug to bug through coprophagy and cannibalism (BB) $A \rightarrow B \rightarrow C$ (From Piekarski 1987)

fluid is microscopically inspected for motile parasites. However, rapid results are obtained in blood cultures. Serologic investigations help during the chronic phase. When using IFT, ELISA, KBR, or IHA in about 90 % of the cases, positive results are obtained. PCR gives best results even in the chronic phase; however, this method is not everywhere available. In regions, where *T. rangeli* occurs besides *T. cruzi*, differential diagnostic has to be done before treatment is started.

Infection

Trypomastigotes enter the skin via the biting channel after the bug has excreted a drop of feces containing parasites. **Attention:** Infections may also occur during blood transfusions or rarely via breast feeding of babies.

Prophylaxis

Disinfection of dwellings by use of insecticides.

Incubation Period

Five to twenty days until occurrence of edemas close to biting sites (e.g., at eyelids).

Prepatent Period

One to two months.

Patency

Often years.

Therapy

Most effective is ► **nifurtimox** (Lampit®) during both acute and chronic phases (8–10 mg/kg bodyweight (children 15–20 mg/kg) daily for 3–4 months). Benznidazole (Radanil®,

Rochagan®) in a dose of 5–7 mg/kg bodyweight daily for 60 days is also effective. However, tissue damages that had been existing before treatment will not be healed.

Trypanosoma epinepheli

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This flagellate parasitizes in the blood of farmed brown-marbled grouper fish (*Epinephelus fuscoguttatus*) in China. This parasite is characterized by a mean body length of 22.3 µm (17–25 µm), a narrow body width (1.7 µm), and a central nucleus and a rather long flagellum (mean 10 µm). The kinetoplast is situated about one quarter of the body length from the posterior end.

Trypanosoma equinum

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This parasite is the agent of disease of the so-called **mal de caderas** in South America. It occurs in horses; however, the agents of disease are also found in reservoir hosts like cattle, dogs, capybara, etc. The transmission occurs apparently

mechanically by contact with tabanids, biting flies, and licking flies but also by activity of blood-licking bats. The trypomastigote agents of disease look like dyskinetoplastic *Trypanosoma evansi* stages (if they are even not a strain of this species). The disease shows the following symptoms: phases of edemas, paralysis, loss of weight, and weakness, which persists chronically. **Diagnosis:** The disease can be diagnosed by serological tests (IFAT, ELISA, DAT). **Treatment** can be done by products used in *T. brucei* infections. However, 3.5 mg/kg body weight diminazene (i.m. application) does not clear fully the parasitemia (Fig. 1).

Trypanosoma equinum,

Fig. 1 Light micrograph of trypomastigote stages of *T. brucei*, *T. equinum*, and *T. evansi*. Langform = long stage; Kurzform = short stage

Trypanosoma equiperdum

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *trypanon*: boring system; *soma* = body.
Latin: *equus* = horse; *perdere* = to lose.

Geographic Distribution/Epidemiology

Worldwide, disease of horses and donkeys, however, in Europe only in Southern countries; e.g., in

Germany last cases occurred in the year 1953, same status in the USA and Australia. However, reimport is always possible due to horse trade as was proven by, e.g., outbreaks in Italy 2008 ongoing.

Morphology/Life Cycle

The trypomastigotes reach a length of up to 25 µm and are found in early phases of infections in lesions of the genital system, later on they enter also the blood vessels and are transported into the brain, too. Their morphology is similar to that of *T. brucei evansi*.

Symptoms of Disease (Dourine)

The spreading of the disease runs slowly. After infection, at first lesions occur in the mucous layers of the genital systems of the most important hosts: mare and stallion. These lesions are accompanied by slimy excretions. In the case of **stallions**, the following symptoms predominantly occur: swelling of the penis and lymph nodes, frequent excretions of urine. In the case of **mares**, frequent excretions of urine occur too. Furthermore, swellings of the vagina and vulva are seen in the mares, which further on show symptoms of permanent mating activity. Later both sexes show white spots at the outer skin of the sexual organs being named “toad dots.”

Trypanosoma equiperdum, Fig. 1 Light micrograph of a Giemsa-stained trypomastigote of *T. equiperdum*

***Trypanosoma equiperdum*,**

Fig. 2 Swelling of the scrotum/penis of a *T. equiperdum* infected stallion (Fig. from Prof. Dr. Heydorn, Berlin)

***Trypanosoma equiperdum*,**

Fig. 3 Swelling of the vulva of a *T. equiperdum* infected mare (Fig. from Prof. Dr. Heydorn, Berlin)

Again, later the disease leads to generalized symptoms such as spots of urticaria (3–5 cm in diameter) at the skin of neck, shoulder, breast, etc. These wheals persist for 3–4 days; however, new ones are formed during the next months. Phases of paralysis, ptosis, strabismus, mydriasis, lagophthalmos, etc., and several phases of polyneuritis finally occur. During this period relatively high rates of mortality have been described in literature.

Diagnosis

This disease must be announced to the government veterinary authorities after a definitive diagnosis has been obtained by microscopical

investigation of Giemsa-stained smear preparations of the excreted slime and by use of serological methods such as KBR and ELISA (Fig. 1).

Infection

The agents of disease are transmitted during sexual intercourse between stallion and mare and probably by mechanical transmission via mouth-parts and legs of flies (Figs. 2 and 3).

Prophylaxis

Regular serological examination of mares and stallions.

Incubation Period

Often 2–3 weeks.

Prepatent Period

5 days.

Patency

Years, if untreated.

Therapy

Treatment is mostly not allowed by veterinary authorities. In case of very valuable animals, exceptions may be allowed. In these cases, the use of trypanosomicidal products such as suramin (Naganol[®]) or Quinapyramin (Trypacide[®]) is recommended.

- Lucian M et al (2013) IgG antibodies from dourine infected horses identify a distinctive *Trypanosoma equiperdum* antigenic pattern of low molecular weight molecules. Vet Immunol Immunopathol 151:140–146

Trypanosoma Genome

Genome sequences showed that in the haploid stage *T. brucei* has a genome size of 25 megabases and about 9,068 genes. *T. cruzi* is provided with a genome of 55 Mb and 12,000 genes, while *Leishmania major* has 33 Mb, but only 8,311 genes.

Trypanosoma Lytic Factors (TLFs)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Trypanosoma lytic factors (TLFs) are very effective toxins that are produced by humans and that provide sterile protection against several African trypanosomes. They attack the parasitic stages (e.g., trypomastigotes) and bind to the trypanosome haptoglobin/hemoglobin receptor (HpH6R). They traffic to the lysosome, lead to membrane damages, and thus induce finally cell lysis. However, the agents of human ► [African trypanosomiasis](#) (*T. brucei rhodesiense*, *T. brucei gambiense*) have developed independent mechanisms of resistance to TLF killing.

Trypanosoma rangeli

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

1. **Name:** Greek (*trypanon*, boring system, and *soma*, body). The name honors the South American scientist Rangel.
2. **Geographic distribution/epidemiology:** This parasite occurs in Guatemala, El Salvador, Costa Rica, Panama, Columbia, Venezuela, and Brazil. Exact data on spreading in

humans are scarce, since this parasite is not very – if at all – pathogenic.

3. **Morphology, life cycle:** Trypomastigote stages were transmitted to humans within the saliva during bites especially bugs of the genus *Rhodnius* (e.g., *R. prolixus*) (salivarian transmission in contrast to the fecal transmission in the case of *T. cruzi*). Many mammalian species act as reservoir hosts. The injected stages reach a length of 30 µm (*T. cruzi* has a maximum length of only 20 µm). Their DNA-containing kinetoplast remains tiny, whereas that of *T. cruzi* is considerably larger. Inside humans and in reservoir hosts, no intracellular stages are found. Thus the parasites stay within the blood fluid, from where they are taken up easily by other vector bugs. Their total number in the peripheral blood is rather low. Inside the gut of the bugs, reproduction occurs as epimastigote stages, which become transformed to trypomastigotes during their way from the intestine to the salivary glands.
4. **Symptoms of disease:** Mostly none, if at all present.
5. **Diagnosis:** ► **Xenodiagnosis** is the method of choice, since the numbers of trypomastigotes in the blood of humans and/or other hosts are very low. Within 2–13 weeks after the bug's sucking, epimastigotes can be found in the intestines of the test bugs. This diagnosis is necessary to exclude *T. cruzi* infections, since in such a case medicaments with strong side effects must be used. **Attention:** In case of the use of serologic methods, cross-reactions may occur with *T. cruzi*. Thus the methods are not very reliable to differentiate between *T. cruzi* and *T. rangeli*.
6. **Infection:** Bites of infected bugs inject saliva containing trypomastigotes.
7. **Prophylaxis:** Disinfection of human dwellings using insecticides with a persistent efficacy.
8. **Incubation period:** Unknown, since mostly no symptoms of disease occur.
9. **Prepatent period:** 1 week.
10. **Patency:** Years.
11. **Therapy:** Not necessary – therefore the exclusion of a *T. cruzi* infection is absolutely needed.

Trypanosoma Species in Neotropical Bats

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Bats occur worldwide, and many species have been described to be vectors of agents of diseases such as rabies, severe acute respiratory syndrome, Ebola disease, and/or fungal infections but also of flagellates that introduce ► **Chagas disease** (► *Trypanosoma cruzi*). In case of ► **blood-licking** vampire bats, it seems reasonable that bats may transmit these trypomastigotes, which occur in the blood of many animals and humans in South and Central America. However, it was found that also fruit-feeding or insect-feeding bats might act as vectors of *T. cruzi*. This can be explained by the fact that they feed also infected bugs. Then the trypomastigotes stay in their saliva, respectively, in their mouth. Thus they might contaminate fruits, by means of which humans might become infected. Although pathways of infections are still unclear, it is a fact that bats of the following species had been found positive for *T. cruzi*, *T. evansi*, *T. dionisii*, and *T. theileri*: *Carollia perspicillata*, *Myotis oxyotus*, ► *Desmodus rotundus*, *Rhynchonycteris naso*, and *Artibeus planirostris*. The prevalence rate of infections with these trypanosomes reached up to 80 % in some examinations, indicating that direct contact with bats or contact to their saliva and/or feces might be dangerous. Apparently many bats host also own species of the genus *Trypanosoma*, e.g., *T. pifanoi* is probably transmitted by sandflies to bats.

Trypanosoma Species of Amphibians

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Amphibians harbor a broad spectrum of species, the cell body of which appears striated when studied by light microscopy. The stages of the different species range from 54 to 78 μm in length, their anterior pole is pointed, and the flagellum surpasses the anterior end by one half or one third of the body length. For example, *Trypanosoma diemyctyli* of newt or eft. Vectors are leeches (e.g., *Batrachobella picta*). Other described species are *T. ambystoma* of the Pacific coast newt or *T. granulosa*, *T. rotatorum*, *T. ranarum* in frogs (e.g., *Rana pipiens*).

Trypanosoma Species of Animals

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *trypanon* = boring system; *soma* = body. Zulu: *nagana* = disorientated, depressed. Latin: *saliva* = spittle, saliva; *vivax* = alive; *brucei* = honoring Sir David Bruce (1855–1931); *congolense* = from Congo river;

Geographic Distributions/Epidemiology

The *Trypanosoma* species of the salivarian type have their main endemic regions in Central East and West Africa, but also in some other regions of Africa since today animal transports are rather frequent. *T. vivax* is most frequent in West Africa, *T. congolense* in East Africa. The trypanosomes infect as well ruminants as equids.

Morphology/Life Cycle

All species (Table 1) live extracellularly as trypomastigote stages in the blood stream of their hosts and reproduce themselves by longitudinal binary fission, which starts at the terminal end (region of the kinetoplast and the origin of the single flagellum) (Fig. 1). There are three main species that lead to a disease in their animal hosts, which is called “**nagana**”:

1. ***Trypanosoma brucei***: This species is found to parasitize rarely cattle and mainly horses. In the peripheral blood two different stages occur:
 - (a) **Stumpy, short forms**, which measure about 15–24 μm in length. Their flagellum does not become free at the anterior end.
 - (b) **Long, slender forms** with a free ending flagellum, which reach a length of up to 39 μm (Fig. 2).
2. ***Trypanosoma vivax***: This species, which parasitizes in equids and ruminants, appears only as slender forms measuring 18–27 μm in length (Fig. 3).
3. ***Trypanosoma congolense***: This species is very small reaching only a length of 9–18 μm ; however, it is very actively moving in fresh blood. It occurs as monomorphic stages and their flagellum mostly does not surpass the anterior end (Fig. 3). *T. congolense* was also

Trypanosoma Species of Animals, Table 1 Important *Trypanosoma* spp. parasitizing in humans and domestic animals

Species	Size (µm)	Vertebrate hosts	Disease	Vector	Mode of transmission	Geographic distribution

^aThe stumpy blood stages are always somewhat shorter (± 10 µm)^bAccording to its main transmission mechanism it belongs to the Salivarian group

Trypanosoma Species of Animals,

Fig. 1 Diagrammatic representation of stages in the life cycle of *Trypanosoma* species. *B* basal apparatus, *F* flagellum, *K* kinetoplast, *N* nucleus, *T* flagellar pocket

Trypanosoma Species of Animals, Fig. 2 Light micrographs of Giemsa-stained stages smear preparations of *T. brucei*, *T. equinum*, *T. evansi*. Note that in *T. brucei* dimorphous stages occur (stretched long form and short = stumpy form)

found in carnivores besides ruminants and equids.

All three species occur not only in the biotopes (rain forests, savannahs, light forests) of the tsetse flies (► *Glossina* species) but also in mountain regions, where they were transmitted mechanically by ► *tabanids* and by biting flies.

If a tsetse fly has ingested slender trypomastigotes respectively stumpy forms, these stages are transformed to epimastigotes in the intestinal tract (see Fig. 4). After repeated binary fission, these stages enter the salivary glands and are transmitted during the next blood sucking acts of the tsetse fly. In *T. vivax* reproduction occurs exclusively in the proboscis of the tsetse fly. In *T. congolense* reproduction occurs in the whole intestinal tract, while stages of *T. brucei* reproduce as well in the intestine as in the salivary glands. The development of the metacyclic (infectious) stages takes 5 days (*T. vivax*) up to 3 weeks (*T. brucei*). Besides this cyclic transmission also mechanical transmissions may occur. Besides the above mentioned hosts of the three *Trypanosoma* species also many reserve hosts occur, from where the parasites may become transported to the specific ones. All these hosts, which are primarily infected with the three above described species, may also serve as reservoir

Trypanosoma Species of Animals, Fig. 3 Light micrographs of trypomastigotes of the species *T. vivax* and *T. congolense*

Trypanosoma Species of Animals, Fig. 4 Light micrograph of stages of the *T. lewisi* group

hosts for the human species *T. b. gambiense* and *T. b. rhodesiense*.

Symptoms of Disease (Nagana, Trypanosomiasis)

The severity of the disease depends on the strain of the injected *Trypanosoma* species and on the susceptibility of the infected host species. Some hosts are even tryptolerant, i.e., although a persisting infection is present they do not show symptoms of disease. The symptoms of disease vary according to the species:

T. vivax lives in the blood stream and does not enter tissues, thus then no lesions occur in the tissues. *T. congolense* and *T. brucei* are also found in the fluids of the cavities of various organs. Thus they introduce not only intense anemia, but their presence initiates also necrotic reactions, inflammations, and fever. In the case of *T. congolense* also glomerulonephritis was seen. Since infected animals are less mobile, they feed less. Therefore increasing weakness and loss of weight may lead to death. However, wild hosts and several endemic hosts practically do not show symptoms of disease, although parasites are present in their organs.

Diagnosis

Microscopical investigation of stained blood smears or of fresh blood (looking for mobile stages) after the Lanham concentration method. Hereby blood is filtered by help of a DEAE-cellulosis membrane. IFAT and ELISA tests deliver also safe results as do PCR tests.

Infection

Trypomastigotes are injected during ► [bites](#) of tsetse flies (as regular vectors) but also during mechanical transmission of parasite containing droplets of blood during sucking of e.g., tabanids.

Prophylaxis

Use of repellents on the fur of farmed animals and application of insecticide-impregnated nets around grazing farm animals.

Incubation Period

One to three weeks depending on the species.

Prepatent Period

One week.

Patency

Months, or until death of infected animals!

Therapy

Therapy is difficult. Drug of choice is recently diminazene (aceturat) = Berenil[®], Ganasep[®] giving 3.5 mg/kg bodyweight im and ethidium bromide (1 mg/kg bodyweight) im. In case of resistances the doses must be increased.

Trypanosoma Species of Fish

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

1. **Name:** Greek, *trypanon* = boring system, *soma* = body.
2. **Geographic distribution/epidemiology:** Worldwide as well as in salt water as in freshwater.
3. **Morphology/life cycle:** There exists a broad spectrum of species (e.g., *T. percae* in the perch species, *T. granulorum* in eels, or *T. carassii* (syn. *T. danilewski*) in carps). These often very large species (15–130 × 2–5 µm) are transmitted by bloodsucking leeches, which, e.g., belong to the genera *Hemiclepsis* and *Piscicola* in freshwater fish and, e.g., *Pontobdella* and *Trachobdella* in saltwater fish. The trypomastigotes inside the blood of fish are transformed to slender epimastigotes inside the intestine of the leeches, which reproduce by permanent binary fissions. After transforming into metacyclic trypomastigotes, the parasites migrate into the region of the proboscis and are injected

into the new host during the next blood meal. The complete development inside the leech takes about 10 days until this vector may transmit the parasites to other fish. *Trypanosoma epinepheli* n. sp. was recently described in farmed brown-marbled grouper (marine fish) in China. This flagellate measures $17.6\text{--}25.9\text{ }\mu\text{m} \times 1.3\text{--}2.0\text{ }\mu\text{m}$ and has a free flagellum surmounting the anterior end for $7.4\text{--}13.3\text{ }\mu\text{m}$ (Fig. 1).

4. **Symptoms of disease:** Mostly asymptomatic. In case that fish are stressed by environmental problems or are crowded in

numbers, the parasites may introduce loss of weight, weakness, anemia (white gills), diziness, or protruded eyes in their hosts.

5. **Diagnosis:** Microscopical inspection of a Giemsa-stained blood smear showing trypomastigotes. In unfixed fresh blood, the parasites can be seen by their movements.
6. **Infection:** Bites of bloodsucking leeches.
7. **Prophylaxis:** Practically not possible.
8. **Incubation period:** 1 week.
9. **Prepatent period:** 1 week.
10. **Patency:** Months or even lifelong.
11. **Treatment:** Incubation in water containing Flagellol[®] of Fa. Sera, Heinsberg, Germany (for fish in aquaria).

Trypanosoma Species of Reptiles

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The knowledge on *Trypanosoma* species of reptiles is rather poor compared to that on

Trypanosoma species of cattle, horses, humans, birds, etc. Many species (e.g., *T. butantanense*, *T. varani*, *T. salamante*, *T. phylodriasi*) had been described in their reptile hosts; however, the life cycles remained mainly in the dark. Phylogenetic analyses of species from snakes showed similarities to those of lizards. Thus the newly described species *T. serpentis* from the snakes *Pseudoboa nigra* and *T. cascavelli* from *Crotalus durissus/terrificus* belong to the lizard/snake clade too. However, vectors are mostly unknown but are surely different, when final hosts live in water or in land biotopes.

Trypanosomatidae Clades

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Maslov et al. (2013) distinguished eight well-defined clades of this group of flagellated protozoans and several not yet named ones:

- 1. **Trypanosoma clade**
The numerous species of the genus ▶ *Trypanosoma* are based on monophyletic ancestors and may infect practically all classes of vertebrates using predominantly vectors such as Diptera, Heteroptera, and Siphonaptera and eventually bloodsucking leeches. These species occur worldwide.
- 2. **Leishmania clade**
The species of this group are very numerous and especially well characterized, since they

can be easily cultured. Species like *Crithidia fasciculata* are included.

- 3. **Phytomonas clade**
The members of this monophyletic group occur most common as parasites of plants being transmitted worldwide by heteropteran bugs.
- 4. **Blastocrithidia clade**
Four defined species are hereunder submitted, *B. triatomae*, *B. leptocorides*, *B. cyrtomeni*, and *B. largi*, which all live inside heteropteran hosts. Type species is *B. gerridis* parasitizing the water-surface runner *Gerres* sp.
- 5. **Leptomonas clade**
This clade is considered as an obscure sister group of the *Blastocrithidia* living in the gut of Heteroptera.
- 6. **Endosymbiont-bearing clade**
Main common sign of the members of this clade (e.g., *Strigomonas*, *Herpetomonas*, *Angomonas*) is the fact that all bear endosymbionts. They all live inside Diptera and Heteroptera.
- 7. **Herpetomonas clade**
Several other species of the genus *Herpetomonas* are included hereunder, which all are defined by the morphological sign that they occur as opisthomastigotes (i.e., the

flagellum starts at the posterior end). They occur worldwide as parasites of ► [Diptera](#), ► [Heteroptera](#), and ► [Siphonaptera](#) and may be kept easily in cultures.

8. *Sergeia* clade

This clade contains rather few known species, which as *S. podlipaevi* occur in midges and can be cultivated easily.

density lipoprotein (HDL/40 % lipid) of about 500 kDa, while TF₂ has only 2 % lipid and a size of 2 mDa. Besides resistance the trypanosomes avoid the contact with the toxic TLP by repeated change of their surface layer. Thus only those single stages survive, resist, and avoid contact, while all other are killed. But in very pathogenic strains, large amounts of new stages are formed again by binary fission.

Trypanosome Lytic Factors

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Humans possess powerful, naturally occurring toxins, which in principle allow them to survive attacks of human African trypanosomiasis (HAT), since they may provide a sterile protection. These trypanocidal complexes penetrate into the trypomastigote stages by binding to their haptoglobin/hemoglobin receptor (HpHbR), trafficking to the lysosomes and finally causing lysis by damage of the cell membrane. However, especially some strains of *T. brucei gambiense* and *T. b. rhodesiense* have developed independent resistance against these trypanosome lytic factors (TLFs), which have been defined as TFL₁ and TFL₂ occurring in human blood and contain both apolipoprotein A-I, apo L-I, and Hpr. In addition TFL₂ contains considerable amounts of IgM. TFL₁ is a minor subclass of human high-

Trypanosomiasis, Animals

Synonyms

Trypanosomosis

General Information

Trypanosomosis is a cardiovascular system disease (► [Cardiovascular System Diseases, Animals](#)) which results from infection with protozoan parasites of the genus ► [Trypanosoma](#). With the exception of *T. equiperdum*, the cause of ► [dourine](#), they are all transmitted by haematophagous arthropods, such as kissing, bugs for *T. cruzi* (the cause of ► [Chagas' disease](#) in South America), biting flies for *T. evansi* (the cause of ► [Surra](#) in Asia, central America, and North Africa), or bloodsucking flies of the genus ► [Glossina](#), for *T. congolense*, *T. vivax*, and *T. brucei* (the cause of ► [Nagana](#) in Africa).

Therapy

► [Trypanocidal Drugs, Animals](#).

Trypanosomiasis, Man

The following trypanosomes commonly have been found in humans: *T. brucei gambiense* and *T. b. rhodesiense* (► [Sleeping Sickness](#)), *T. cruzi* (► [Chagas' Disease, Man](#)), and *T. rangeli*. The first 3 produce disease; the last gives rise to asymptomatic infection in Latin America and must be distinguished from the less frequent, but pathogenic *T. cruzi*.

Since *Trypanosoma cruzi*, restricted to America, is a mainly intracellular protozoan parasite, while the African trypanosomes (*T. brucei* sp.) live extracellularly, the immune defense mechanisms against these parasites as well as the mechanisms of pathogenesis are distinct (► [Chagas' Disease, Man](#)/► [Immune Responses](#), ► [Sleeping Sickness](#)/► [Immune Responses](#)).

Therapy

► [Trypanocidal Drugs, Man](#).

Trypanosomiasis, Rhodesian

Trypanosoma brucei rhodesiense infection occurs in East and Central Africa. It is characterized by a rapidly progressive clinical course and often leads to death within months, in the third stage of the disease, without pronounced central nervous system involvement. The early course of the disease, ► [chancres](#) and parasitemia, is similar to the Gambian disease. Fever and lymph node enlargement are especially prominent, often with myocarditis, weakness, ► [weight loss](#), preceding death. Myocarditis is characterized by the presence of lymphocytes and plasma cells, and is accompanied by trypanosomes in myocardial cells and by pericardial effusion.

Therapy

► [Trypanocidal Drugs, Man](#).

Trypanothione

Gluthathione (GSH) is replaced by trypanothione (TT), a glutathione dimere, that is reduced by trypanothione reductase.

Trypanoxyuris atelis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This pinworm species, which belongs like 17 other species to the genus *Trypanoxyuris*, has been described to induce mass infections in nonhuman primates in zoological gardens by constant autoinfections, which may cause chronic diarrheas associated with pruritus ani and indirect behavioral problems. A related species (*T. microon*) affects owl monkeys (*Aotus nancymae*).

Trypomastigote Small Surface Antigen (TSSA)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes a surface glycoprotein of the trypomastigote stage of ► *Trypanosoma cruzi*. It is involved in the host cell invasion by the parasitic stage.

Trypomastigotes

Developmental stage of ► *Trypanosomatidae* (► *Trypanosoma*, Fig. 5) living mostly free in the blood of vertebrate hosts. The flagellum arises from a significant ► *flagellar pocket* that is situated at the rounded end of the parasite, while the flagellum becomes free at the pointed end (► *Flagella*).

Tsetse Flies, Overview

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

African, *tse-tse* = biting fly; naming, flight noise.

Classification

Family of insects, genus ► *Glossina*.

Synonyms

Glossinidae.

General Information

Fossil Glossinidae are about 30 million years old. About 23 species belong to this family of the ► *Diptera*, of which males and females feed exclusively on blood. Only a few species are vectors of human ► *sleeping sickness*, but all are potential vectors of animal trypanosomiasis.

Tsetse flies possess large, widely spaced eyes, forward-projected mouthparts, and wings which cover at rest the whole abdomen horizontally, like closed blades of a pair of scissors. Tsetse flies are holometabolous insects, with females giving birth to full-grown larvae which rapidly pupate in the soil.

Distribution

Tsetse flies occur nearly exclusively in an area of about 11 million square km in the tropical rain forest and the savannah woodland. The population density is generally low.

Morphology

Tsetse flies are 6–14 mm long (Figs. 1 and 2, *Glossina*/Figs. 1–5), excluding the ► *proboscis*. The broad head bears three ocelli and two large compound eyes which are widely spaced in both sexes. The pair of short antennae has three segments and each an arista with its characteristically branched hairs. Hygro-, thermo-, chemo-, and mechanoreceptors are concentrated on the antennae. The mouthparts consist of three unpaired components, the piercing labium, the labrum enclosing the food channel, and the hypopharynx with the salivary channel. All are sheathed by two modified maxillary palps. On the back, the thorax ends in a caudal, triangular scutellum. The eight abdominal segments can distend greatly after feeding. Males and females can only be distinguished by the genital organs, males possessing a button-like hypopygium under the dorsal end of the body which covers the clasper. The white larvae are elongated, without eyes and legs, at the posterior end possessing a pair of black

Tsetse Flies, Overview,

Tsetse Flies, Overview, Fig. 2 Magnification of the mouthparts prior to injection into the skin

polypneustic lobes. Like in ► [Muscidae](#), the pupae develop in the tanned skin of this final third larval ► [instar](#), and the adults emerge from the ► [puparium](#) by means of the ► [ptilinum](#), a

Tsetse Flies, Overview, Fig. 3 Scanning electron micrograph of a *Glossina morsitans*

region on front of the head which can be ejected and retracted and hardens later.

Genetics

Genetics of different populations of species are investigated to identify loci for different enzymes and those responsible for refractoriness to the trypanosomes in order to combat ► [African trypanosomiasis](#) by the release of genetically modified vectors.

Tsetse Flies, Overview,

Fig. 4 Diagrammatic representation of a tsetse fly (genus *Glossina*). (a) Dorsal view. (b) Antenna with three segments with a so-called arista. (c) Mouthparts in lateral view. (d) Mouthparts cross-sectioned. *AB* abdomen, *AR* arista, *D* discoidal field, *FA* compound eye, *HA* haltere, *HY* hypopharynx containing food transport channel, *LA* labrum, *LB* labium, *MT* mesothorax, *N*, food transport channel, *O* ocellus, *PT* prothorax, *T* metathorax

**Reproduction**

Breeding of tsetse flies in the laboratory is possible but labor-intensive, either by feeding them on living hosts or in vitro through membranes.

In nature, males search for the females near the hosts. Both have fed at least 2 times before mating. Contact sex-recognition pheromones in the ► [cuticle](#) help to avoid interspecific pairing. During copulation a ► [spermatophore](#) is produced and filled with sperms. Usually females mate only once. They have two ovaries and each of

them two ovarioles in which eggs develop sequentially. About 9 days after emergence of the female, the ovulation and fertilization of the first egg occur, about 9–10 days later the second, and so on. After ovulation, a relict body remains in the ovariole, thereby allowing determination of the number of depositions of larvae at least for the first 4 ones. Females live several months – at 25 °C about 80–100 days – and can survive long periods of starvation. During this period each female can deposit only about 10 full-grown larvae.

Tsetse Flies, Overview,

**Biochemical/Molecular Data**

Biochemical techniques, e.g., enzyme electrophoresis and gas chromatography of cuticular hydrocarbons, and DNA probes have been successfully used to distinguish between morphologically similar species or at least to classify them into one of the 3 groups of ► *Glossina*. Other biochemical/molecular biological investigations focus on changes in the reproductive cycle, the endosymbionts, and the rickettsia-like organisms. PCR is mainly used to identify infected tsetse flies.

Life Cycle

Also in tsetse flies the duration of the respective developmental phase is temperature dependent. The following data are based on a development at 25 °C, unless otherwise stated. Eggs are not deposited, but after an embryonic development of

about 4 days, the first instar larva hatches within the uterus. It is nourished by “milk” glands, a pair of modified accessory glands. The first instar is held in position within the uterus by a sticky material, the second one by uterine ► **ridges**, and the third one by the wall of the uterus. The duration of these three instars is 1, 1.5, and 2.5 days, respectively. The first two instars respire through posterior ► **spiracles**, but the third instar develops posterior polypneustic lobes. The mature larva is about 5 mm long and weighs about 35 mg, heavier than the female. The deposited larva excretes the waste products and burrows into the soil, and within an hour after larviposition, it pupates. At a mean temperature of 30 °C, the puparial development needs 20 days and at 20 °C additional 27 days. About 1 h after emergence, the adult fly, termed “teneral” fly, is capable of flight but needs about 10 days to complete the development of cuticle and flight muscles. Bacterial symbionts, which are restricted to special organs

(► [mycetomes](#)) near the gut and are transmitted transovarially or by the milk to the progeny, are necessary for adult reproduction (*Glossina*/Fig. 5).

Transmission

Tsetse flies can fly at speeds of up to 25 km per hour, but they usually fly more slowly and only for short periods of time, e.g., up to 50 min. Usually tsetse flies rest more than 23 h per day in trees to avoid desiccation. Dispersal distances of 100–200 m per week are covered, but under optimal conditions 2 km per day can be covered. Tsetse flies do not need carbohydrates as fuel for flight but can use the amino acid proline derived from the blood meal.

Feeding Behavior and Transmission of Disease

The diurnal tsetse flies are induced by breath and urine components of the host to fly upwind. Near the host they orientate visually, responding more strongly to moving than stationary hosts. Colors are discriminated, blue being particularly attractive. The different species prefer different regions of the body of the host for bloodsucking. The bites of tsetse flies usually result in a minimal skin reaction. The mouthparts of tsetse flies enter a capillary directly or suck from a little open pool of blood. Ingested blood (40–80 mg or more) is first pumped into the midgut and, if this is distended maximally, then into the crop. At the beginning of the midgut, the ► [peritrophic membranes](#) are made to enclose the blood. In the anterior region of the midgut, the blood meal is concentrated, not digested. This takes place in the middle region, and absorption in the posterior region of the midgut. Within 2 days nearly all of the blood is digested.

Tsetse flies transmit human and animal trypanosomiasis. The causative agents for sleeping sickness (► [sleeping sickness](#)) are *Trypanosoma brucei gambiense* and *T. b.*

rhodesiense. *T. b. brucei*, *T. congolense*, and *T. vivax* attack cattle and *T. simiae* pigs.

Interaction of Vector and Parasite

When the tsetse flies suck blood, the further development of the trypanosomes depends on the species of ► [Trypanosoma](#). *T. vivax* only colonizes the proboscis and *T. congolense* and *T. simiae* the midgut and the proboscis, whereas *T. b. gambiense*, *T. b. rhodesiense*, and *T. b. brucei* develop different stages in different regions of the intestine. This seems to occur only in “teneral” tsetse flies taking the first blood meal, whereas old flies are refractory, perhaps due to the action of rickettsia-like organisms or stronger peritrophic membranes. After ingestion, the stumpy ► [trypomastigotes](#) transform in the midgut to procyclic trypomastigotes, also changing the surface coat. After colonization of the ectoperitrophic region and penetration of the anterior peritrophic membranes, they migrate to the foregut and colonize the salivary glands presumably via the salivary duct. Penetration of the wall of the gut and migration in the hemolymph to the glands have also been postulated. In the glands, they transform to epimastigotes which possess no surface coat and attach to the ► [microvilli](#) of the glands. This stage transforms to metacyclic trypomastigotes which finally make a new surface coat.

Effects of the parasites have been reported by different investigators, while others did not observe such effects, perhaps due to the choice of strains of flagellate and vector. In susceptible systems, the parasites interfere with the blood ingestion, perhaps by an attachment to mechanoreceptors in the proboscis which register the speed of the ingested blood. In addition, carpets of flagellates in this region should also affect the blood flow, and damage to the salivary gland the recognition of blood vessels. Thereby, infected flies probe more often and need more time for a blood meal. Minor effects are the development of more bacteria in the intestinal tract of infected flies and reduction of intestinal microvilli. The longevity of infected adults seems to be

unaffected or only slightly reduced, but insecticide resistance is clearly reduced.

Prophylaxis

Since the flies are active outdoors during the day, no ► [prophylaxis](#) is possible.

Control

Originally, clearance of the vegetation around the villages reduced the number of bites by tsetse flies. However, this is labor-intensive and has to be repeated. All tsetse flies can be killed using insecticides: aerial application is complicated by the low population density of the fly; ground application techniques reduce the side effects on other animals. Trapping seems to offer the best protection. Traps made of blue cloth, baited with ox urine, impregnated with insecticides, and located around the villages strongly reduce the number of attacks. The effect could be increased by screens. The sterile-male technique has also been used successfully, but on a long term, most areas cannot be protected from reinvasion.

Bait Methods for Control

Tsetse host-finding behavior can be used as a specific method of controlling these parasites with low environmental impact. Numerous traps and targets have been developed which kill attracted tsetse flies with insecticides. The highly effective devices that are presently in use attract the flies visually by their form and color and chemically by host odor components such as acetone, butanone, 1-octen-3-ol, 4-methylphenol, 3-methylphenol, and 3-*n*-propylphenol. Further research on host finding of the lesser studied *Glossina* spp. and on other attractive components of host odor may improve the effectivity of the traps (insecticides).

Host Finding

In tsetse flies, in contrast to mosquitoes, both sexes obligatorily feed on blood, so there is no interference between host-finding behavior and sugar feeding. However, the physiological state of the flies, such as circadian rhythm of activity and excitability, age, sexual activity, and nutritional state, as well as ► [environmental conditions](#), may modify the host-finding behavior. Host finding is best known in *G. morsitans* and *G. pallidipes*, two species which behave relatively similarly. However, other species show very different host-finding strategies, and even populations of the same species may differ in their behavior. Host signals have an influence on the fly's activation, on the oriented flight toward the host, on alighting and probing, and on ingestion of food.

Activation

The great mass of a tsetse population is normally at rest, and it has been suggested that most tsetse flies spend only 10–30 min in active flight daily. Resting or flying (ranging) tsetse flies are activated by visual, olfactory, or mechanical host cues. The effectiveness of the activating visual stimuli depends on size, shape, pattern, contrast with the background, color, and movement. Carbon dioxide, acetone, acetic acid, 2-hexanone, and certain phenolic compounds have been identified as activating chemicals, and they may be involved in the effect of cattle odors. However, 1-octen-3-ol, a component of cattle breath which attracts tsetse flies, has no activating effect.

Oriented Flight

In their flight toward the host over longer distances (up to more than 90 m), the tsetse flies use chemical cues. They follow the airstream downward of the host by an odor-regulated

upwind anemotaxis. As stimulating compounds of cattle odors, carbon dioxide, 1-octen-3-ol, acetone, and several ketones and aldehydes have been identified, and certain phenolic compounds of cattle urine (e.g., 4-methylphenol, 3-methylphenol, and 3-*n*-propylphenol) were attractive as well. However, host odors are more attractive as their isolated compounds. They in fact contain unknown additional attractants which eventually might be effective only in combination, not as single chemicals.

At close range the chemically attracted tsetse flies orient to the host using visual cues. The visual characteristics which maximally attract tsetse flies have mainly been studied using traps, which may also include attractive components related to behavioral patterns other than ► [host finding](#), e.g., to search for resting sites or refuges. The attractiveness of visual bait depends on its shape, size, movement, contrast versus background, color, and pattern. Surprisingly, some of the factors which increase the attractiveness of visual bait have only little in common with characteristics of the hosts. For example, biconical bait attracts much more tsetse flies than do animal-shaped traps. The most attractive color is royal blue with a high reflectivity at 650 nm (mid blue) and low ultraviolet reflectivity, characteristics which are very unusual in nature. Generally, the attractiveness of a surface is increased by blue and red reflectivity and diminished by ultraviolet and green-yellow reflectivity. Uniformly colored bait attracts more tsetse flies than that with stripes and complex patterns, probably because they have a higher contrast to the background patterns. It was speculated that this may be linked to the evolution of the stripe pattern of zebras, on which tsetse seldom feed.

Tsetse flies can be activated and attracted by visual stimuli alone. They then move to an area just downwind of the bait. This may enable the flies to distinguish a possible host from nonanimal materials by odor. This behavior may also be involved in mate finding, as it can produce a localized swarm downwind of the bait. Warm

body radiation and moist convection currents, which strongly attract mosquitoes, seem to have no influence in tsetse host identification.

Alighting and Probing

The tendency of tsetse flies to land on bait is intensified by movements of the bait, by increased size, by chemical cues such as carbon dioxide, and by unknown components of cattle odor and sebum, but not by the attractants 1-octen-3-ol and phenolic compounds. The flies in addition prefer to land on dark surfaces or on surfaces with strong reflectivity in the ultraviolet wavelengths. That ultraviolet increases the number of landing flies, but inhibits their attraction, might have a simple explanation: ultraviolet reflectivity is typical of skylight, and the increased landing rate of the flies might be the result of accidental collisions with “transparent” surfaces, rather than the result of normal alighting responses. Probing is stimulated by a temperature gradient and odors, whereas engorging seems to depend on the adenine nucleotides ATP, ADP, and AMP, as well as on salts in the diet.

This term describes a system of channels which are induced by *Plasmodium falciparum* as soon as a merozoite has been enclosed by a parasitophorous vacuole (PV) inside an erythrocyte. This system is involved in nutrient uptake and enlarges considerably the surface of the originally balloon-like parasitophorous vacuole.

Tularemia

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

This disease received its name with respect to the district Tulare in California (USA), where in the year 1912 the two American scientists McCoy and Chapin isolated a bacterium from a squirrel showing plaque-like symptoms of disease and called it *Bacterium tularensis*. Since 1974 this agent of disease is listed as *Francisella tularensis* honoring **E. Francis**, who detected the relations between the plaque-like symptoms of rodents, rabbits, etc.,

and the symptoms of humans, which had been described by varying names such as deer fly fever, Ohara's disease (in Japan), Francis' disease, Market men's disease, rabbit fever (in the USA), or as lemming fever (in Norway). The second species *F. philomiragia* is found in waters of the Atlantic and in the Mediterranean Sea but is of low virulence.

Geographic Distribution/Epidemiology

The agents of disease are distributed in their animal hosts (rodents, rabbits, hares, beavers, etc.) in countries of the northern hemisphere (the USA, China, Japan, Europe) with cold or moderate climates. In these countries also humans become infected, but symptoms of disease remain often low graded and thus are not detected. For example, in the USA it is calculated that only one human case occurs among one million inhabitants (~300–400 cases are noted per year). In Germany and in other European countries also, only rare cases are found within a year, although local epidemics had been described in Scandinavia and South Europe. Infected people turned out to belong mainly to groups such as hunters, forest workers, and joggers but also has been described in more than 100 animals.

Morphology/Life Cycle

The bacteria are small coccoid (0.2–0.7 μm), non-motile, strictly anaerobic, gram-negative organisms, which grow predominantly inside cells (e.g., macrophages) being enclosed in a capsule. Transmission occurs by bites of contaminated mites, ticks, or blood-sucking insects and by contamination of open wounds. There are shown four subspecies, where *T. holarctica* is most virulent.

Symptoms of Disease

At the sites of entrance, papulae are formed leading in addition to local lymph node swellings.

Eyes may be infected, too, as well the oropharyngeal system by subsequent contamination. The infection of the respiratory system is most dangerous and lethality without antibiotic treatment is high (30–60 %). Thus the disease has to be announced to local health authorities.

Diagnosis

Microscopic inspection of agents of disease in open wounds, but mostly reproduction in tissue cultures is needed. Isolated material may also be investigated by serological methods (ELISA, immunofluorescence) or by PCR.

Infection

Mechanical transmission during bites of blood-sucking arthropods or by flies, which have contaminated feet; inhalation of infected tick feces. In dead animals these bacteria remain infectious for up to 40 days. Already 10–40 inoculated bacteria are sufficient to establish a patent infection.

Prophylaxis

Avoid bites or contacts to insects and ticks of wild animals.

Incubation Period

Two to fourteen days.

Prepatent Period

Seven to fourteen days.

Patency

Months, even longer in animals.

Therapy

Streptomycin ($2 \times 0.5\text{--}1$ g/day for 1014 days, intramuscularly) or gentamicin (2×2.5 mg/kg bodyweight per day).

Tumbu-Fly Disease

Myiasis due to the larvae of the fly *Cordylobia anthropophaga* (► [Myiasis](#), [Man](#)).

Tumor Necrosis Factor (TNF)

TNF is produced by macrophages and has a synergistic effect with nitric oxide (NO), that produces highly toxic peroxynitrite and hydroxyl radicals. TNF- β is one of the most important cytokines in context to immunity against infectious diseases.

Tumor Necrosis Factor α (TNF- α)

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This is an inflammatory cytokine and pyrogen, which is primarily suppressed by macrophages

but also by T cells and B cells. It promotes apoptotic cell death and supports control of pathogens when activating, proliferating, and differentiating leucocytes.

Name

Indian: *tung* = penetrating organism; Latin: *penetrans* = penetrating

Classification

Species of fleas, Aphaniptera, family Tungidae

General Information

Tunga penetrans is endemic today in dry regions of the tropics in South and Central America, the Caribbean, the whole sub-Saharan Africa, Madagascar, Zanzibar, Seychelles and Comoros

***Tunga penetrans* Linné, 1758, Fig. 1** (a–d) Life cycle stages of the jigger or sand flea *Tunga penetrans* which parasitizes human and animals in tropical and subtropical regions. (a) Male (temporarily bloodsucking). (b) Unfed female (1 mm long). (c) Inseminated females enter the skin (of feet) and feed the head down. (d) Fully grown, pea-sized female starts producing eggs (in total about

200) which fall to the ground. Having laid her eggs the female dies. The infested tissues may become ulcerated and infected with other pathogens. The larvae hatch from the eggs and start the typical cycle of fleas which takes about 3 weeks. AB abdomen, CO copulatory organ, EP epidermis of host skin, SA swollen abdomen, SW swelling abdomen

Islands. The female flea causes tungiasis, an infectious disease of the skin. The fleas belong to the rare zoonotic parasite species which spread successfully from the Western to the Eastern Hemisphere. The natural origin is South America. *Tunga penetrans* was introduced verifiably into Angola in 1872 and spread successful over sub-Saharan Africa. Sporadically, cases are reported from India, Pakistan, and Europe, but the infections are acquired in endemic regions before or result from imported specimens. *Tunga*

penetrans occurs in altitudes below 2 km. It is not host specific and attacks many warm-blooded hosts such as canids, cats, cattle, rats, and other rodents, as well as humans and pigs. Older reports of birds as hosts of *T. penetrans* are based presumably on misidentification and confusion with species of the closely related *Hectopsylla*. The unfed males and females (Figs. 1 and 2) are only 0.8–1 mm in length. They are thus one of the smallest species out of the approx. 2,000 world-wide known species of fleas. According to the

embedded lifestyle of females, they lack any flea typical combs on the pronotum and head. Coxae are comparatively weakly developed and limit capability to jump. By the help of their sword-

***Tunga penetrans* Linné, 1758, Fig. 2** LM of the head of a female with its strong, sword-like sawing mouthparts

like mouthparts (Fig. 2), the females (Fig. 3) penetrate the head forward (comparable to the stick-tight flea ► *Echidnophaga gallinacea*) into the host's epidermis and start growing for about 3–4 weeks while drinking blood. Especially, the region of the second and third abdominal segments becomes enormously enlarged (Figs. 4, 5, and 6), so that the whole flea finally reaches diameters of up to 1 cm. The males (Fig. 3) copulate with penetrated females several times, and only after each copulation they suck blood. On day 6 after penetration and after a copulation, the females start to eject daily up to 200 large ovoid, about 600 µm-sized eggs through genital opening, which fall to the ground. The genital opening contrasts from the further abdomen and is visible as a dark area to the naked eye (Fig. 5). Larval development in the eggs takes about 3–4 days. The two larval stages grew up via one molt within 5–11 days and then start pupation, which takes 4–7 days. It was recently shown by comparing *T. penetrans* fleas from different hosts that there might be two different groups, since those of humans, pigs, and dogs differ in some morphological and molecular biological features from those of cats and rats. In contrast to the former belief that *Tunga* fleas were imported around 1900

Classification

Genus of fleas, Aphaniptera, family Tungidae

General Information

The genus *Tunga* (Tungidae) (Jarocki 1838) contains 13 described species so far. Main reservoir hosts are Artiodactyla, Xenarthra, Rodentia, and Felidae. Three species (*Tunga hexalobulata*, *T. penetrans*, *T. trimamillata*) are known to parasitize in domestic animals, the last two infest humans, too, causing tungiasis. The genus is divided systematically into *caecata* and *penetrans* groups with respect to host range and morphological characteristics. Most members are distributed naturally in South and Middle America. Recent distribution of *Tunga penetrans* includes Africa. *Tunga callida* and *T. caecigena* occur naturally in China and Japan. Origin of genus is probably the Neotropics. The genus belongs to the most basal and together most specialized flea lineage. Maximal length of gravid females (*T. travassosi*) amounts 13 mm. Characteristic feature of females of the genus is to form neosomy (Greek: neos = new, soma = body) after penetration in host skin and to lay eggs while embedded. Neosomy in arthropods describes a remarkable enlargement as well as formation of new external structures in instar or adult stages (intrastadial metamorphosis) based on secretion of new cuticle outside of the regular molt. Neosomy usually occurs in interspecific association between species like the parasite-host interaction of *Tunga* females, but it is also seen in other arthropods, e.g., acari and termites. Main features are the ingestion of large amount of food or preparation of egg production (Table 1).

Tungidosis

General Information

Tungiasis is an infection of the epidermis, usually the foot, with sand fleas of the genus *Tunga* (*T. penetrans* and *T. trimamillata*) usually acquired by walking barefoot on moist sand or soil in the tropics (Figs. 1, 2, and 3). Predilection site of penetration is the periungual region of the feet, heels, and soles. But the flea can penetrate at

any side of the body. In small children ectopic sites are the hands, elbows, neck, anus, and genitals. A number of specimens on infected man can extend up to several hundreds. Inhabitants of poor

communities are more frequently infected and suffer under a higher grade of infection than other population groups. Tungiasis follows a typical seasonal variation with the highest prevalence within the dry season. The parasitic stage is a mated female flea which attaches to the skin. It feeds on blood, enlarging in size up to about 1 cm in diameter when eggs develop. The flea becomes surrounded by keratin except for the head, which extends into the papillary dermis. The whole tumor is surrounded by chronic inflammatory reaction including eosinophils. The flea sucks blood and has a digestive tract which ends superficially where the keratin layer is incomplete. Large numbers of eggs develop in the flea and are discharged to the outside. The flea dies when it has discharged all of its eggs, its body collapses, and an intraepithelial abscess develops which eventually drains and heals. As consequences of penetration and remaining dead females in host skin, risk of secondary infections exists. Moreover, problems are untreated or insufficient treated lesions after the removal of hypertrophic female. Several pathogenic bacteria are associated with lesions like *Clostridium tetani*, *Streptococcus pyogenes*, pathogenic *Staphylococcus aureus*, *Klebsiella aerogenes*, *Enterobacter agglomerans*, and *Escherichia coli* another *Enterobacteriaceae*. Pustule formation, ulceration, lymphangitis, gas gangrene, tetanus, deformation of digits, loss of toenails, and sepsis are possible sequelae. The flea larvae live in the soil. After pupation, mating

Tungiasis, Fig. 1 Foot of a child with penetrated females

Tungiasis,

Fig. 4 Inflammatory lesions and embedded female of *Tunga penetrans* in the sole of a giant anteater (*Myrmecophaga tridactyla*). The fleas have even penetrated the rough sole what results in limitation of movement and digging behavior

occurs; the male flea dies after copulation, the place of which is not yet fully understood; and the female flea attaches to the foot of any of a number of hosts and burrows into the keratinaceous layer.

Treatment and Prevention

Effective therapeutics against embedded females are not known yet. Therefore, the only protection consists in the use of repellents and preventive killing of eggs, larvae, and adults. Wearing shoes hardly provide protection against infection with *T. penetrans*. To avoid skin attaches, coconut oil-based (Zanzarin®) or Saltidin-/vitex extract-based (Viticks®) repellents are suited. The only effective therapy against embedded females still consists in the operative removal of hypertrophic individuals as soon as possible or to place a drop of oil on just penetrated stages. Especially the female dies after penetration and following egg position and may lead to mentioned secondary infections. Community studies showed that adults are more frequented than children and boys more than girls.

Tungiasis in Wild and Production Animals

Tungiasis is an infection of the epidermis of wild and production animals. All thirteen species of the genus *Tunga* parasitize on wild animals, and only

T. penetrans and *T. trimamillata* are known to infect humans (Tungiasis in humans) (Figs. 1 and 2). Main hosts (*Tunga* spp.) include Rodentia, Xenarthra (Figs. 3 and 4), and Ungulates. Productive livestock is susceptible for infections with *Tunga* spp. and can form the most important animal reservoir in endemic areas. Especially *T. hexalobulata*, *T. penetrans*, and *T. trimamillata* are known to infect ungulates. In cattle, main penetration sides are perioplic corium and interdigital skin that leads to locomotion problems. In pigs, also the feet are mainly infected that complicates natural movement. Teats can be infected heavily that can lead to undersupply of piglets. The fleas can even penetrate rough soles of digging mammals (Fig. 1) and cause secondary infections. In endemic areas, pig livestock can form the most important animal reservoir of *T. penetrans*, followed by dogs and cats as well as rodents.

Twaitia

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Twaitia is a genus of nematodes (so-called dragon worms, family Dracunculidae), which suck blood

at fish (e.g., below the operculum of the gills) and thus appear bloody red. They give rise directly to active larvae 1, which mostly do not leave the original host. However, these larvae can also become ingested by crustaceans and thus transported to other fish. **Treatment** in aquaria can be done with levamisole or fenbendazole.

Twinnia

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Twinnia is a genus of the subfamily Prosimuliini among the so-called black flies (family ► *Simuliidae*).

Tylodelphys clavata

Trematode species (family Diplostomidae) parasitic on the eye lenses of fish (gobies) in the Baltic Sea and Black Sea. *T. excavata* inhabits as adult stage the intestine of stork (*Ciconia ciconia*), the intermediate hosts are the snail *Coretus corneus* (first) and frogs (second), where the metacercariae are formed.

Typhloceras poppei

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Flea species of rodents (Fig. 1).

***Typhloceras poppei*,**

Fig. 1 Light microscopical lateral view of a female flea from rodents

Typhus exanthematicus

Synonyms

Louse-borne Typhus; Spotted Typhus
Human disease due to infection with *Rickettsia prowazekii* transmitted via feces of lice.

Tyrolichus casei

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *tyros* = cheese, *lichen* = covering.

Tyrode, Maurice Vejux (1878–1930)

French pharmacologist, famous for his buffer, that is still used in many culture systems and is similar to the salt contents of the blood serum.

Synonyms

Tyrophagus casei.

Tyroglyphus

Genus of mites of the family Tyroglyphidae with feed grain dust; they may induce allergic reactions in man and birds or may transmit bacteria (*Salmonella*) in bird stables.

Morphology

Mite species, which reaches as adults a length of 0.5–0.7 mm. Specimens appear ovoid, whitish with reddish legs (Fig. 1). They live on/in different cheese but also on other organic material, if it is not too dry. This species is also cultured and added to some commercial cheese types.

***Tyrolichus casei*, Fig. 1** DR of the ventral side of an adult male

Disease

Some people show allergic reactions upon contact with such mites (so-called para- or pseudomange). Others suffer from abdominal pain, and diarrhea, if they eat such mite cheese.

Tyrophagus putrescentiae

Mite that feed *Aspergillum* fungi or grains; skin contacts or inhalation may lead in humans to itching and other allergic reactions.

Tyvelose

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

A sugar residue characteristic of secretory proteins of larval stages of ► *Trichinella spiralis*, which are highly antigenic.

Tyzzer, Edward Ernest

American scientist, discoverer (1912) of the genus *Cryptosporidium*.

Tyzzeria

Genus of ► *Coccidia* of ducks. The oocysts contain 8 sporozoites, but no sporocyst.

U

Uitpeuloog

Infection with *Gedoelestia* larvae (► [Diptera](#)) leading to thrombo- and endophlebitis in animals, as well as to the bulging eye disease of cattle (► [Cardiovascular System Diseases, Animals](#)).

Ulcer

Clinical and pathological symptom of infections with skin parasites (► [Skin Diseases, Animals](#), ► [Ectoparasite](#)).

Ulcera de Bauru

Symptoms due to infections with *Leishmania braziliensis*.

Ultrasound

This method is now sensitive enough for a significant diagnosis of alveolar echinococcosis, anisakiasis, ascariasis, echinococcosis, fascioliasis, lymphatic filariasis, paragonimiasis, and schistosomiasis.

Umingmakstrongylus pallikuukensis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

So-called small protostrongylid nematode (lungworm) of muskox, which was recently described in the Canadian Arctic.

Uncinaria

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Latin: *uncinatus* = hooklike.

Classification

Genus of the nematode family Ancylostomatidae.

Uncinaria, Fig. 1 LM (above) and SEM of the anterior pole of adult worms

Uncinaria, Fig. 3 LM (above) and SEM of the posterior end of a male

Uncinaria, Fig. 2 LM and SEM of the anterior pole of adult worms

General Information

Specimens of *U. stenocephala* (Figs. 1, 2, 3, 4, 5, and 6) are found worldwide in zones with moderate climate and live in the small intestine of canids (occasionally also in felids, rarely in pigs). The adults (female, 4–16 mm; male, 3–11 mm) suck

Uncinaria, Fig. 4 LM and SEM of the posterior end of a male

Uncinaria,

Fig. 6 Diagrammatic representation of the life cycle of hookworms of the genera *Ancylostoma*, *Necator*, *Globocephalus*, and *Bunostomum*. 1.1 Mouth region with species-specific hooks. 1.2 Posterior bursa copulatrix of males. 2–5 Eggs are excreted at 2–6 cell stage and develop outside the larva 1, which hatches from the egg. 6–10 Larval development. Finally the larvae 3 form tree-like accumulations on grass so that by contact to a host mostly several larvae 3 enter the skin. 11–12 Larvae 3 may creep in skin regions (11) or reach finally the intestine after a heart-lung-trachea-esophagus migration. AN anus, E esophagus, IN intestine, NR nerve ring, R fortifying rays of the bursa copulatrix, SH sheath, T tooth

blood by means of their buccal capsules, which is provided with 2 bladelike cutters (Figs. 1 and 2). The **prepatent period** is 14–17 days; the typical hookworm eggs are ovoidal and reach a size of $70\text{--}90 \times 35\text{--}60 \mu\text{m}$. The infections of the final hosts occur by oral uptake of the free-living, sheathed larvae 3 (there is no skin penetration). Two days after uptake the larvae hatch from the sheath in the stomach or in the duodenum and reach maturity after 2 molts already in 14–18 dpi. The **patency** lasts 4–6 months. Some of the larvae 3 are able to survive in paratenic hosts (rodents). By feeding such infected hosts, the canids/felids may also become infected. In contrast to other hookworms, a prenatal or lactogenic transmission of worm larvae to the puppies does not occur.

Disease

Heavy infections introduce retarded growth, loss of weight, slimy diarrhea as well as hypoproteinemia.

Diagnosis

Microscopic finding of the ovoidal eggs showing 4–16 blastomeres in fresh feces.

Therapy

Nematocidal Drugs.

Uncinaria hamiltoni

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Hookworm of the South American sea lion *Otaria byronia* and of the Australian fur seal *Arctocephalus pusillus* doriferus. Males measure 9–12 × 0.3–0.4 mm; females measure 16–25 × 0.4–0.5 mm.

Uncinaria lucasi

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Hookworm of the northern fur seal *Callorhinus ursinus*.

Uncinaria sanguinis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

► [Hookworm](#) in Australian sea lions (*Neophoca cinera*).

Further Reading

Undifferentiated Cell

They occur in ► [Platyhelminthes](#) and are able to develop into all other specialized cells. In ► [hydroids](#) and in the alveolar cysts of the *Echinococcus* spp. they divide constantly, thus giving rise to the growth of the brood capsules and the formation of the infectious protoscolices. They are still omnipotent.

Undulating Membrane

In the ► [trichomonads](#) and in the trypomastigote stages of trypanosomes, a flagellum may be connected to the cell surface by ► [desmosomes](#) (► [Trypanosoma](#), Fig. 5). The recurrent flagellum is attached in this manner so that when it pulls the plasma membrane (► [Plasmalemma](#)) away from the body, the undulating membrane is created (► [Trichomonadida](#), Fig. 1C).

Unguitractor

Thornlike structure at the last tarsal segment of *Cimex* bugs.

Ungulata

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Latin: *ungula* = hoof. Latin name for animals in the group of ruminants and equids.

UNICEF

United Nations' (International) Children's
(Emergency) Fund.

Unilocular Cysts

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Echinococcus granulosus, ► [hydatids](#) (Fig. 1).

Unthriftiness

Clinical symptom in animals due to parasitic infections (Alimentary System Diseases, Clinical Pathology, Animals).

Unilocular Cysts, Fig. 1 Macrophoto of several unilocular cysts (= hydatids) of *Echinococcus granulosus* in a liver of a sheep

Urinary System Diseases, Animals

Parasitic infections of the urinary system are not of major importance in domestic animals. Clinical signs are generally absent, or not seen, and the presence of the parasites is often only detected incidentally through the observation of sporocysts, eggs, or fragmented worms in the urinary sediment. Only few species of nematodes (*Capillaria plica*, *C. feliscati*, *Diocotophyma renale*, *Stephanurus dentatus*) and protozoa (*Klosiella equi*, *Eimeria truncata*) inhabit the urinary system of domestic animals (Table 1). In addition, migrating nematode larvae (e.g., *Toxocara canis* in dogs) or *Schistosoma mattheei* in cattle, may occasionally invade the urinary system and lead to the formation of small granulomas around the larvae or eggs. Protozoa such as *Babesia* and *Leishmania* may induce excessive immunocomplex formation thus causing glomerulonephritis. ► [Haemoglobinuria](#) (or ► [“red water”](#)), a clinical sign which may be caused by ► [Babesia](#) multiplying in erythrocytes, is not associated with the presence of parasites in the urinary system.

K. equi is found in the convoluted tubules of the kidney in the horse and its relatives. These sporozoan parasites cause a destruction of renal epithelial cells, and histopathological examination of the kidneys may reveal an interstitial nephritis

Urinary System Diseases, Animals, Table 1 Parasites affecting the urinary system of domestic animals (according to Vercruysse and De Bont)

Parasite	Host	Location	Clinical presentation	Principal lesions
Protozoa				
<i>Klossiella equi</i>	Horse	Kidney	None	Interstitial nephritis
<i>Eimeria truncata</i>	Goose	Kidney	Diarrhoea, weakness, ataxia	Tubulonecrosis, interstitial nephrosis
Trematoda				
<i>Schistosoma</i> spp.	Ruminants	Kidney, bladder	Haematuria	Granuloma formation around eggs
Nematoda				
<i>Capillaria feliscati</i>	Cat	Bladder, sometimes the pelvis of the kidneys	Mostly asymptomatic, in heavy infections haematuria, dysuria, and pollakiuria	Light inflammation of bladder mucosa
<i>C. plica</i>	Dog, fox, wolf			
<i>Diectophyme renale</i>	Dog, mink, cat, fish-eating mammals, rarely horse, pig, man	Free in abdomen, kidney	Asymptomatic when one kidney is involved, otherwise uremia may occur	Kidney parenchyma (usually right) is destroyed, often only the capsule being left
<i>Stephanurus dentatus</i>	Pig	Perirenal fat and adjacent tissues	No typical signs, weight loss	Adults: cysts, filled with greenish pus

in some animals. However, the infection produces no clinical manifestation of disease. *Eimeria truncata* develops in epithelial cells of renal tubuli in geese. The kidney appears swollen showing many white or yellow foci. Young geese are highly susceptible and may die due to tubulonecrosis and interstitial nephrosis.

The trichurid nematodes *Capillaria plica* and *C. feliscati* live in the urinary bladder and occasionally the ureters and renal pelvis of dogs and cats, respectively. They are about 3–6 cm long and produce little or no pathogenic effect, probably because of the superficial attachment of the worms to the epithelium of the urinary bladder. However, the parasites may occasionally invade the mucosa and cause an inflammatory reaction, leading to haematuria, dysuria, and pollakiuria.

The giant ► **kidney worm** *Diectophyme renale* occurs in the kidneys and peritoneal cavity of the mink and dog and other fish-eating mammals, but has also occasionally been found in the pig, cattle, horse, and man. In the dog, adult worms have primarily been found in the peritoneal cavity, which suggests that it is not a natural definitive host of the parasite. *D. renale* is the largest known

nematode. Female worms may reach up to 100 cm in length and the pathogenesis of the infection is related to the considerable space that the parasite takes inside the renal pelvis. The enlargement of the cavity occurs at the expense of the ► **parenchyma**, to such an extent that the kidney may eventually be reduced to an empty capsule. Partial obstruction of the ureter may also take place, leading to hydronephrosis. The severity of clinical disturbance and outcome of the infection depend on the ability of the host to maintain a normal renal function. In dogs, the right kidney is more frequently invaded than the left. Such unilateral infection generally leads to a compensatory hypertrophy of the opposite kidney, and does not cause clinical disturbance. When both kidneys are parasitized the animal may die of uraemia without sufficient time for extensive pathologic changes to develop in the kidneys. Although the presence of adult worms in the abdominal cavity has occasionally been associated with ascites and haemorrhages, it does not usually cause clinical signs.

► *Stephanurus dentatus*, the kidney worm of swine, is generally found in the perirenal fat and

adjacent tissues. About 2–4 cm in length, these worms form cystic cavities that communicate with the renal pelvis and allow the eggs to be passed in the urine. Most of the pathogenesis of this tropical and subtropical parasite is related to its larval stages. They are particularly aggressive in the liver where their migration causes severe inflammatory reactions and eventually results in extensive portal fibrosis. The adult parasite encysted near the ureters is not markedly pathogenic, although thickening of the ureters and cystitis have occasionally been reported. Aberrant migration of *S. dentatus* to other abdominal or thoracic organs where it causes local purulent tissue reaction, appears to be a common feature. As in many helminthosis of the pig, the major clinical sign in most infections is a failure to gain weight.

The urinary form of schistosomiasis in domestic animals appears to occur only in cattle heavily infected with *Schistosoma mattheei*, a parasite of the mesenteric and hepatic portal veins of ruminants in southern Africa. The lesions in the urinary bladder may range from scattered individual granulomas with petechia to widespread polypoid and granular patches. Urinary manifestations such as haematuria are rare and seen only in super infected animals.

Therapy

See entries of the different species.

Urodela

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *ura* = tail; *delos* = visible. Group of amphibians with a long, visible tail, e.g., salamander.

Urogenital Schistosomiasis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This human diseases, which often ends with urogenital bladder cancer, is a consequence of long-lasting, nontreated infections with ► *Schistosoma haematobium*.

Urogonimus macrostomus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This digenean trematode of the family Leucochloridiidae reaches a length of up to 2 mm and lives in the cloaca of “singing birds” (e.g., Passeriformes). Intermediate hosts are amber snails (Succineidae), where sporocysts are formed. Inside these sporocysts, cercariae and finally metacercariae are developed, which give rise to adult trematodes after the snails have been ingested by the birds (final hosts). A peculiar behavior (► *Peckham’s mimicry*), which leads to the fact that the sporocysts enter during daytime into the tentacles of the snail and initiate 40–70 heavy contraction per minute and thus enhance the chance to be noted by birds, which are the final host. A similar behavior is described from ► *Leucochloridium macrostomum* (also in amber snails). In both cases the tentacles of the snail become considerably stretched so that the brown, green and orange through shining sporocysts can be seen.

Uroid

Terminal region of some protozoa, e.g., amoebae, where excretion is done by inner vacuoles with the outer cell membrane (► [Exocytosis](#)).

Uroproctepisthmium bursicola

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Trematode of the family Echinostomatidae (life cycle; see *Echinostoma*), which parasitizes as larvae in fish. Thus also humans may become infected, if they ingest raw fish.

Institut Pasteur, Paris, France

Long before the parasites and the causes of parasitic diseases were known, it was observed that if an individual recovered from a disease, rather than succumbing to it, he rarely developed the same illness again. It must have been these types of observations that led people in Asia some hundreds of years ago to deliberately infect infants on the backside with infective material from ► [Leishmania](#) lesions (► [Leishmanization](#)), thus inducing an immunity that protected immunized individuals from reinfections with disfiguring lesions

(► [Immune Responses](#)). After **Edward Jenner** in **1796** succeeded in immunizing a young boy with material from cowpox blisters against a challenge infection with smallpox, the first attenuated live vaccine (after “vacca,” the Latin word for cow) was born. Up to now the vast majority of successful vaccines against virus, bacteria or parasites are attenuated live vaccines based on the principle that avirulent organisms can confer protection against virulent, disease-causing pathogens (► [Vaccination Against Nematodes](#), ► [Vaccination Against Protozoa](#), ► [Vaccination Against Platyhelminthes](#), ► [Amoebiasis](#), Chagas' Disease, Animals, ► [Chagas' Disease, Man](#), ► [Trypanosomiasis, Animals](#), ► [Trypanosomiasis, Man](#), ► [Leishmaniasis, Animals](#), ► [Leishmaniasis, Man](#), ► [Malaria](#), Toxoplasmosis, Animals, Toxoplasmosis, Man).

Vaccination Against Nematodes

Vaccine research always has to compete with the development of anthelmintics. Whereas the latter increasingly cover a broad range of endo- and even ectoparasites, vaccines are efficient against only one parasite species. However, with increasing resistance of parasites against anthelmintics and ecological awareness about drug residues, vaccines become more and more important.

Irradiation Attenuated Live Vaccines

The first and undoubtedly most successful anti-nematode vaccine to date is the irradiation attenuated live vaccine against the bovine lungworm, ► *Dictyocaulus viviparus*. Following the observation that cattle who survived natural infections with ► *D. viviparus* larvae obviously developed a degree of immunity that protected them from clinical disease after a natural challenge, first immunization trials were carried out in the mid-1950s. It was soon found out that crude preparations of somatic antigens from adult worms or larvae did not stimulate sufficient active immunity to prevent the disease. It was then assumed that the stimulation of protective immunity might depend on substances which were only elaborated by living worms. After intensive search for methods to weaken the infective larvae without killing them, X-ray irradiation proved to be the method of choice. Whereas irradiation below 200 Gy did not produce a sufficient degree of alteration of the larvae, 600 Gy considerably damaged the larvae which failed to stimulate a protective immunity. Eventually best results under both experimental and field conditions were obtained by two oral administrations of 1,000 infective, 400 Gy attenuated third-stage larvae, each, 4 weeks apart. This vaccine was launched on the market in 1958 and has been commercially available ever since (Dictol[®], Bovilis[®], Intervet).

Vaccination with irradiated lungworm larvae does not confer a sterile immunity. During subsequent challenge infections animals are protected against clinical disease and worm burdens are reduced by 95–98 %, but low numbers of worms may reach maturity and produce new larvae. Immunity from vaccination protects for up to 12 months (similar to a single natural infection), i.e., for the following grazing season. If no natural infections booster the immunity, animals are susceptible to disease again thereafter. Therefore, vaccination is recommended for endemic *D. viviparus* areas, where natural boosts can be expected and lifelong protection may be achieved.

Although calves may be vaccinated already from 2 weeks after birth the vaccine usually is administered to susceptible calves in early spring.

The second immunization has to be given at least 2–3 weeks before turnout to pasture. Within 2 weeks after the last vaccination no anthelmintic treatment should be given.

As freezing kills the larvae and higher temperatures reduce their life span, the vaccine must be stored between 2 and 8 °C. Under these conditions the shelf life is 3 months.

The mechanism of X-ray attenuation is unknown. It has been speculated that irradiation induces abnormalities in protein structure producing highly immunogenic molecules, which in their normal configuration are only weak immunogens. However, they still have to be common enough to native antigens to stimulate an immune response that is able to interact with antigens from normal organisms. Besides modified antigen conformation additional modes of action have been discussed, such as prolonged exposure of particular antigens, induction of specific cytokines and dynamics of cell-mediated responses.

The mode of action of the irradiated *D. viviparus* live vaccine and the relevant antigens have not been identified yet. Efforts have been made to identify protective antigens on a molecular level and will be described under “Recombinant vaccines.”

The successful vaccination of cattle against *D. viviparus* inspired the initiation of a similar programme and the production of a commercial vaccine against *D. filaria* in sheep in India in 1971 and Iraq shortly thereafter. Infective, third-stage larvae are irradiated with 500 Gy. As with bovine lungworms, irradiated larvae confer high levels of immunity when given orally to young lambs in two doses of 1,000 and 2,000 larvae, 4 weeks apart. Without reinfection protection lasts between 12 and 24 months and varies between sheep breeds. The efficacy of the vaccine has been demonstrated under experimental and field conditions. Within the first 10 years about 360,000 sheep in endemic areas had been successfully vaccinated, however the demand is much higher and by far exceeds the production capacity of the vaccine producers. The vaccine is also used for the immunization of goats. Irradiated larvae have to be maintained at 4 °C and have a shelf life of only 2 weeks.

After irradiation proved to be a successful method to attenuate infective ► [helminth](#) larvae for live vaccines a number of immunization experiments with all kinds of ► [nematodes](#) were carried out. A second, although only temporarily available commercial vaccine was developed against the canine hookworm, ► [Ancylostoma caninum](#) and released in the USA in 1973. After washing and sterilization of eggs collected from faeces, larvae were cultured in sterile medium, harvested by filtration and irradiated (400 Gy). Due to sterile culture conditions, a shelf life of 6 months was achieved at 10–15 °C. The vaccine conferred a high degree of protection but no sterile immunity allowing single worms to become adult and produce eggs. Therefore, the veterinarians preferred the simultaneously introduced modern anthelmintics, which immediately eliminated eggs from faeces. This together with increasing production costs eventually led to the withdrawal of the vaccine in 1975. Trials with 5-fluorouracil or UV attenuated hookworm larvae also showed a considerable degree of protection but remained at an experimental stage.

Immunization experiments with attenuated infective larvae under both experimental and field conditions have been performed with a large number of nematodes (Table 1). Most of them never reached beyond an experimental stage and did not lead to a commercial vaccine. Problems arose with vaccination of young animals. Juvenile animals often are not yet immunocompetent at the time of vaccination or still have maternal antibodies that kill and eliminate vaccine larvae before they can stimulate immunity.

Subunit Vaccines

A major advantage of live vaccines is that during invasion, tissue penetration and development a whole range of antigens is presented and generally a solid protective humoral and cellular immune response is stimulated. However, a major disadvantage is always that shelf life is short and insufficient attenuation may lead to pathogenic effects and the spread of the parasite. Compared to attenuated live vaccines, subunit vaccines

contain only a small number of defined antigens but are safe in that no viable parasites are administered and development and reproduction cannot occur.

One of the nematodes, where major research efforts have been undertaken is ► *Haemonchus contortus*, a sheep nematode that causes major economical losses in sheep breeding countries. Strategies for vaccine development against ► *haemonchosis* basically take two different approaches: (1) identification of “natural antigens” (or conventional antigens), that are presented to the host’s immune system during natural or experimental infections and (2) search for “hidden antigens” (sometimes also called concealed, covert or novel antigens), that are extracted from internal parts of the parasite, mostly the gastrointestinal tract, and that are not “seen” by the host during the course of infection.

Natural antigens usually comprise excretory/secretory (ES) or surface antigens and in *Haemonchus* are mostly derived from the early infective larval stage (L3). In early immunization experiments whole L3 extracts and ES antigens gave no significant protection, whereas a high molecular weight (>30,000) fraction from both antigen preparations reduced wormburdens after challenge by 59 %. Immunization with a purified metabolite of exsheathed in vitro cultured L3 considerably reduced the egg production but not the number of worms. A new approach for the identification of natural protective antigens was reviewed by Newton. It is based on the observation that ► *B-cells* are rapidly recruited to the site of infection with a pathogen and to the local draining lymph node before they migrate into the target tissue and differentiate into antibody-secreting cells (ASC). It was therefore assumed that antibodies secreted by parasite activated B-cells are likely to recognize antigens important in rejection of the parasite by the host. Compared to serum antibodies, ASCs from immune animals, harvested during stimulation by the parasite from the lymph node draining the site of infection, recognized a much more limited and different group of antigens. ASCs isolated from sheep 5 days after a challenge infection with large doses of ► *H. contortus* specifically recognized

L3/L4 antigens at approximately 44–48 kDa and a broad band at 70–83 kDa. These antigens did not react with ASCs from older infections (without challenge) whereas serum from both groups showed complex patterns of antigens, emphasizing the advantage of using ASCs compared to serum. The 70–83 kDa band proved to be a glycosylated L3 surface antigen. Immunization trials with this purified antigen showed a significant reduction in total faecal egg counts (FEC) in vaccinates of 54 % and 50 % in adult worm numbers. Although natural antigens described above conferred only about 50 % protection, efficacy could possibly be enhanced with optimal antigen presentation and different adjuvants.

A number of ES antigens from adult worms and L3 with protease activity have been described and some have been evaluated for their protective potential. Three apical gut surface proteins of adult *H. contortus*, p46, p52 and p100, were able to induce protective immunity to challenge infection in goats. All three proteins are encoded by a single gene, GA1, and initially expressed in adult parasites as a polyprotein, p100GA1. p46GA1 and p52GA1 are related proteins with 47 % sequence identity. GA1 proteins occur in the abomasal mucus of infected lambs, suggesting that they are ES antigens and possibly presented to the host immune system during infection.

In other experiments partly purified low molecular weight antigens obtained by gel filtration of whole worm homogenates or total adult ES antigens were tested for their ability to induce protective immunity against *H. contortus*. Except for one animal low molecular weight fraction vaccinates showed a highly significant reduction of adult worms of 97.6 % and FEC reduction of 99.9 %. Vaccination with ES antigens conferred a lower protection of 63.7 % (adult worms) and 32.2 % (FEC). Further analysis of the ES fraction of adult worms revealed two immunogenic low molecular weight proteins of 15 and 24 kDa, the first not glycosylated the latter containing some glycosylation. Sheep immunized with either fraction showed more than 70 % reduction in worm burdens and FEC, respectively. Corresponding recombinant proteins were isolated from a *H. contortus* L5 cDNA library and expressed in

E. coli. As mRNA encoding both ES products occurred only in the parasitic stages, expression appears to be developmentally regulated. Both recombinant antigens were recognized by sera from *H. contortus* hyperimmunized sheep, suggesting that antigenic determinants were also present on the recombinant proteins. Protein extracts enriched for cysteine protease activity (thiol Sepharose-binding fraction = TSBP) confer substantial protection against challenge infection. Fractionation of these proteins showed that protection is associated with the protease components of the protein. Vaccination with recombinant cysteine proteases did not reduce faecal egg counts and showed a moderate (38 %), but significant reduction in worm burdens.

Whereas immunity against natural antigens is boosted by natural infections, immunity against hidden antigens is not. The hidden antigen strategy has been simultaneously developed for the cattle tick ► *Boophilus microplus* and for the nematode *H. contortus*, both haematophagous parasites. The immunization of an animal against “Achilles’ heels” of the parasite such as surface proteins from the gastrointestinal tract or metabolic or detoxifying enzymes will result in the production of specific circulating antibodies. After ingestion of these antibodies by the parasite they bind to the corresponding antigen and disrupt its structure or function. Although this strategy is most effective in blood feeders the ingestion of immunoglobulins has also been described for non-blood feeding nematodes such as ► *Ostertagia* and *Dictyocaulus*. The first hidden antigen described for *H. contortus* was a polymeric helical structure, associated with the surface of the intestinal epithelium, called contortin. Although immunization trials showed protection levels of >90 % purification proved to be difficult. With the discovery of H11 contortin was not further developed. H 11 (or H110D) is a heavily glycosylated 110 kDa integral membrane protein of intestinal ► microvilli of adult *H. contortus*. DNA and amino acid sequence analysis showed a high identity to mammalian microsomal aminopeptidases. Their function is the cleavage of dipeptide products of digestion to amino acids for transport across the plasma membrane. Therefore

the efficacy of the vaccine is most likely based on the inhibition of enzyme activity and subsequent starvation of the worms for essential amino acids. Numerous immunization trials with different breeds of sheep showed that, unlike irradiated vaccines, H11 is effective in very young lambs already and average protection levels exceed 90 % in terms of FEC reduction and 75 % reduction in worm burdens. The higher effect on egg production is at least partly caused by the fact that the vaccine affects female worms to a greater extent than males. Additionally, surviving female worms are smaller than those from control animals and presumably produce fewer eggs. As the parasites have to suck blood before protective antibodies can be effective, PCV values fall after challenge, but less marked than in controls and animals do not show clinical signs of haemonchosis. Although the native H11 is highly protective and recombinant clones have been produced, there are no reports to date about successful immunization trials with the recombinants. It may be assumed that in vitro expression of the heavily glycosylated protein in both procaryotic and eucaryotic cells does not correctly produce the immunogenic epitopes. Aminopeptidases are functional proteins not only present in *Haemonchus*. Homologues have been described in *Ostertagia* spp. and will most likely be present in numerous nematodes.

During the first steps for the extraction of H11 two additional proteins are co-purified, H45 od also termed P1 and a *H. contortus*-galactose binding glycoprotein (H-gal-GP). P1 is a protein complex that comprises three protein bands on SDS-PAGE of about 53, 49 and 45 kDa. P1 is also localized at the surface of intestinal epithelium cells and has aspartyl proteinase activity. It is assumed that it contributes to the digestion of blood meals and may therefore be a promising vaccine candidate. Immunization trials showed only about 30 % reduction of adult worms and about 70 % egg counts. H-gal-GP is a complex of intestinal surface proteins that appear on non-reducing SDS gels as two main bands at 230 and 170 kDa and two faint bands at 47 and 50 kDa. It is not known whether one of these bands or the complex as a whole confers protection. Immunization with the whole protein

complex showed an average FEC reduction of about 90 % and again a lower efficacy against adult worms with approximately 60 % reduction after challenge. Antibodies raised against the corresponding recombinant antigen bound to the luminal surface of the gut in adult *H. contortus*, but to date no data about protective potential of the recombinant antigen are available. The examples show that gut associated proteins of *H. contortus* proved to be a rich source for vaccine candidates and will be further evaluated.

Although non-blood feeding nematodes do also take up host IgG, to date only natural antigens have been examined for their protective potential in other trichostrongylid nematodes. A complex ES antigen preparation (molecular weight >10,000) of adult *Cooperia punctata* showed various degrees of protection ranging from 16 % to >80 % reduction of worm counts in calves. Immunization trials with ES antigens from exsheathed *Trichostrongylus colubriformis* L3 in guinea pigs showed worm reductions between 0 % and 74 %. Among different protective components an immunodominant glycoprotein of 94 kDa was identified.

In *Ostertagia circumcincta* a 31 kDa glycoprotein (GP31) was identified in secretory organelles within the cells of the oesophageal glands of L3. After in vitro cultivation GP31 was shown to be one of the major components of the ES complex. The purified GP31 had no detectable proteolytic activity in protein degradation assays, but homologues were found in *T. colubriformis* and *H. contortus* L3. Immunization of lambs conferred insignificant reduction in total worm counts and FEC. In immunized animals humoral and cellular immune responses could be detected.

Tropomyosin is a protein of muscle cells of vertebrates but can be found in different isoforms in non-muscle cells such as fibroblasts as well. A 41 kDa tropomyosin has been identified from a detergent-soluble fraction of *T. colubriformis* L3. Immunization of guinea pigs with the 41 kDa antigen induced 43–51 % protection in terms of reduced worm burden after challenge infection. The same antigen was isolated from ► *Acanthocheilonema viteae* and conferred significant protection (up to 65 % reduced adult

worms, up to 95 % reduced circulating microfilariae) in jirds. Recombinant tropomyosin cDNA clones from ► *Onchocerca volvulus* have been used to vaccinate BALB/c mice against challenge infection with *O. lienalis*. Significant reductions (48–62 %) in the recovery of microfilariae from the skin were achieved. Recombinant tropomyosin clones have also been prepared from *T. colubriformis* and *H. contortus*; however, protectivity data have not yet been published.

► **Paramyosin**, a filamental protein, is a substantial part of ► **myosin** filaments in muscle cells of many nematodes. It blocks the actomyosin binding in the contracted muscle cell to make possible a persistent contraction without energy consumption. Paramyosin has been identified as a protective antigen and a major vaccine candidate in schistosomes but also in different nematode species. In filariid nematodes such as *O. volvulus*, ► *Dirofilaria immitis* and ► *Brugia malayi* paramyosin clones have been identified. Immunization of mice with a native 97 kDa paramyosin homologue of *B. malayi* reduced microfilaraemia by 40–60 % after i.v. challenge with live *B. malayi* microfilariae. Vaccination of jirds with a recombinant *B. malayi* paramyosin fused with maltose-binding protein (BM5-MBP) stimulated protection against challenge infection. Adult worm recoveries (43 %) and female worm length (10 %) were significant, blood ► **microfilaria** counts slightly reduced compared to MBP vaccinated controls.

The early success and the introduction of a commercial live vaccine against *D. viviparus* in cattle seemed to paralyze the research on lungworm immunity and the search for alternative vaccine candidates for the following years. Because vaccination trials with cattle are expensive, most studies on protective antigens were done in a guinea pig model. However, it is well known that the immune response is different from cattle and antigens such as lyophilized worms that proved to be protective in guinea pigs may have no efficacy in cattle. McKeand and colleagues immunized guinea pigs with either somatic extracts of adult lungworms, somatic extracts of L3 or ES products from adults. Only the adult ES fraction conferred more than 80 % protection.

Acetylcholinesterases (AChE) are found mainly in adult stages of many free-living and parasitic nematode species. Secreted AChE are assumed to have an anticoagulant role and affect glycogenesis. Most importantly, however, they seem to have an immune modulatory effect and reduce inflammation in the vicinity of the parasites. The reason why some benzimidazole resistant nematode strains contain elevated amounts of AChE is still unknown. As in many other nematodes AChE activity was also identified in somatic extracts and ES products of adult *D. viviparus*, the latter containing over 200 times more AChE activity than the first. In Western blots AChE was only recognized by serum from naturally or experimentally infected calves and not by serum from irradiated larvae vaccinated animals, suggesting that AChE is secreted only by adult worms. Guinea pigs immunized with the AChE enriched fraction of ES antigens of adult worms showed significant lower worm burdens after challenge. The AChE was successfully cloned but immunization trials with the recombinant antigen in cattle were not successful. A secretory AChE from *T. colubriformis* had already been used to vaccinate against mixed infections of *T. colubriformis*, *H. contortus* and *C. oncophora* with average worm count reductions of 31 % and up to 58 % in individual cases.

In preliminary vaccination trials recombinant methyl transferases showed a substantial degree of protective potential reducing worm burdens and larval counts by more than 50 % while stimulating a strong IgG response.

Vaccination with an ES polyprotein allergen in *O. ostertagi* was able to reduce faecal egg counts by 60 %. Adult worms in the vaccinated animals were significantly shorter. Adult worm ES cysteine protease enriched proteins used in vaccination trials were also able to reduce egg counts by 60 %. Neither of these proteins was successful as recombinant antigen.

Because of its zoonotic importance and lacking prophylactic strategies a vaccine against ► *Trichinella spiralis* would be a great advantage. A preparation of whole newborn *T. spiralis* larvae killed by freezing and thawing induced a high level of protection against challenge. Muscle

larval counts were reduced by 78 % compared to 40 % after immunization with ES antigens from muscle larvae. In a comparative study freeze-thaw/sonicated preparations of newborn larvae, adult worms, muscle larvae and a mixture of all three were used to immunize pigs. Eight weeks after challenge infection muscle larval counts were reduced by 82–93 % (newborn larvae), 66 % (muscle larvae) and 98 % (mixture of all fractions). ES antigen preparations from *T. spiralis* and *T. britovi* conferred significant protection in a mouse model, showing that *T. britovi* was more immunogenic with greater host-protective immunity. A 40-mer synthetic peptide was produced from a 43 kDa immunodominant glycoprotein secreted by *T. spiralis* larvae. Immunization of mice with the 40–80 peptide fraction induced an accelerated expulsion of adult worms from the gut. As this is mainly induced by T-cell-mediated inflammatory events in the intestine, the 40–80 peptide was assumed to induce a protective T-cell response. This was the first time a synthetic peptide was shown to confer protective immunity in an intestinal nematode.

Successful DNA vaccination trials against *T. spiralis* suggest that this may be a promising way of immunization.

Recombinant Subunit Vaccines

The production of purified native antigens of defined quality for a commercial vaccine would be too expensive. Promising subunit vaccine candidates must be produced as recombinant antigens. Although recombinant subunit vaccines hold great promise, they do present some potential limitations. Recombinant subunit vaccines generally seem to be less immunogenic than their conventional counterparts because they are composed of a single antigen. In contrast, conventional vaccines contain a mixture of antigens that may aid in conferring an immunity to infectious agents that is more solid than could be provided by a monovalent vaccine.

Vaccination with recombinant subunit proteins or synthetic peptides is often hampered by a weak immune response due to inappropriate

presentation of the antigen to the host's immune system or the loss of critical immunogenic epitopes during *in vitro* expression. Additionally protein immunization very often stimulates a B-cell response only where a T-cell response is necessary for protective immunity. Such problems may be circumvented by DNA vaccines (also called DNA-based immunization, genetic immunization, naked DNA vaccines, etc.) which has recently emerged as an attractive alternative to conventional vaccines. Numerous studies have already shown that immunization of experimental animals with plasmid DNA encoding antigens from a wide spectrum of parasites leads to protective humoral and cell-mediated immunity. cDNAs encoding protective protein epitopes can be cloned into plasmid vectors containing strong mammalian promoters for high expression. Purified plasmid DNA containing the protective parasite antigen is administered to the host via intramuscular or subcutaneous or intracutaneous injection or needle free application by carbon dioxide pressure (Biojector[®], Bioject Inc.) or with particle bombardment (Gene gun[®], Powderject Inc.). The DNA is incorporated by professional antigen presenting cells and tissue cells and expressed in enough quantity to induce a potent and specific protective immune response. Expression of the protein antigens of interest directly in host cells can provide appropriate tertiary structure for the induction of conformationally specific antibodies, and also facilitates the induction of cellular immunity. Because the vaccine does not contain genetic elements responsible for replication or infectivity, the vaccine itself is safe and cannot cause the disease. DNA vaccine technology has been successfully used to protect against many different viral, bacterial, mycoplasmal, protozoal and worm infections. Except for successful trials with a cestode (*Taenia ovis*) and ► [trematodes](#) (► *Schistosoma* species) preliminary DNA vaccination trials against nematode infections have been conducted to date with ► *A. caninum*. A paramyosin homologue was used to intramuscularly immunize mice and dogs against challenge infection. Preliminary results showed a consistent B- and T-cell stimulation and reduced wormcounts.

As mentioned before, one of the disadvantages of using single clones as vaccine candidates is often the narrow immunogenic spectrum that may lead to an inappropriate immune response compared to conventional vaccines. The current approach to include a large number of cDNAs encoding putative protective antigens without knowing beforehand the protective epitopes is called 'expression library immunization' and comprises the vaccination with several thousand different cDNAs at the same time. DNA vaccine technology is only beginning to exploit its possibilities in parasite vaccine development and as its advantages in terms of production costs, storage conditions, safety and efficacy compared to other vaccines are convincing, it can be expected that the number of vaccination trials against nematodes will increase and possibly will soon lead to the development of a commercial product.

Vaccination Against Platyhelminthes

Dania Richter

Abteilung Parasitologie der Charité
Universitätsmedizin, Institut für Pathologie,
Berlin, Germany

General Information

Requirements of Vaccines Against Multicellular Organisms

The development of vaccines against multicellular parasites, such as platyhelminths, poses particular requirements. Although many vaccines have been developed and marketed to protect against viruses and bacteria, vaccines against parasitic ► [protozoa](#) and ► [metazoa](#) are limited to a few that are available solely for animal use. None has yet successfully been developed which eliminates or eases the burden that multicellular parasites inflict on people. Not only have platyhelminths a far more complex genetic composition than do viruses and bacteria, they also pass through an often complex sequence of

developmental stages that home in to specific sites within their host's body. Thus, the target of an antiplatyhelminth vaccine constantly changes and moves. In ► [coevolution](#) with their hosts, these parasites have acquired sophisticated mechanisms of ► [immune evasion](#). As a result, little or no protective immunity develops even in hosts that are frequently reinfected or superinfected. A vaccine against a platyhelminth ought to target a mixture of diverse antigens.

Advantages of Immunotherapy Over Chemotherapy

Although chemotherapy successfully reduces worm burden resulting from the most common platyhelminth infections, a vaccine would offer added benefits. Whereas a drug removes worms after they have accumulated in the host's body, a vaccine prophylactically limits or even prevents the worm burden. Drug therapy fails to prevent reinfection and necessitates frequent re-treatment; its antiparasitic effect, however, is almost immediate, often acting within hours or days. Immunity resulting from vaccination develops slowly, requiring several months, but continues to protect the host for years, particularly when frequently boosted by exposure to the parasite. Drug resistance of platyhelminths is a common outcome of overuse or inadequate administration of a drug. No such genetic adaptation to vaccine-induced immunity has yet been demonstrated for any pathogen. To combine the immediate but short-term effect of chemotherapy with the slowly generated but long-lasting effect of immunoprophylaxis seems the most desirable strategy.

Reduction of Morbidity Versus Sterilizing Immunity

In contrast to parasitic protozoa, platyhelminths, such as schistosomes, fasciolids, and taeniid ► [cestodes](#), do not divide within their definitive hosts. The worm burden is accumulative and chronic. It differs sharply from the sudden acute attack by rapidly dividing protozoon parasites. Vaccines against parasitic protozoa, such as ► [Plasmodium](#) spp., must produce a sterilizing immunity. Because the ► [morbidity](#) resulting from platyhelminths derives largely from the

intensity of infection, even a partially effective vaccine may benefit the host by reducing pathology. To evaluate the protective potential of an experimental vaccine against platyhelminths, the worm burden resulting from a challenge of vaccinated animals is compared with that of challenged nonvaccinated animals. The degree of pathology can also be compared. Immunoprophylaxis would not only limit morbidity, it may also reduce transmission. If the ► [fecundity](#) of the challenge worms is affected by the vaccine, egg production is reduced, subsequently affecting the transmission of the parasite. A vaccine directed against platyhelminths may be effective in reducing morbidity and limiting transmission, even if it fails to eliminate all worms.

Concomitant Immunity and Acquired Resistance

Infections with platyhelminths rarely induce ► [acquired immunity](#). A particular form of immunity has been described as concomitant immunity. Here, a persisting primary infection confers resistance of the host against a secondary infection with the same pathogen. In the murine model of schistosomiasis, however, it has become evident that the presumed concomitant immunity is an artifact. Pathology induced by granuloma formation affects the portal vasculature and impedes the establishment of schistosomes that arrive with a secondary infection. Platyhelminths have evolved successful mechanisms of immune evasion. Schistosomes, for example, adsorb host molecules on their surface to disguise themselves against the host's immune system. Evidence of acquired immunity against human schistosomiasis remains inconclusive. Although prevalence and intensity of infection decreases with age, children before puberty are completely unprotected.

Parasite Antigens as Vaccine Candidates

Antigen Groups

Fatty acid-binding protein (FABP), a protein of 12–14 kDa, has been described for various platyhelminths, including ► [Schistosoma](#), *Fasciola*, and *Echinococcus*. Similar to its mammalian

counterpart, it is involved in intracellular transport of fatty acids. By electron microscopy, it is detected in lipid droplets in the subtegumental area of male schistosomes and in vitelline droplets of the vitelline glands of female schistosomes. Vaccination of cattle with purified FABP achieves 55 % protection against ► *Fasciola hepatica* and 30 % protection against ► *F. gigantica* (Table 1). It reduces the worm burden resulting from a *F. hepatica* challenge in vaccinated mice by more than 80 %. In FABP-vaccinated outbred mice challenged with *Schistosoma mansoni*, up to 67 % reduction in worm burden may be achieved; in similarly treated rabbits, protection reaches 90 %. Mice and rats vaccinated with either recombinant FABP or DNA vaccine develop 32–39 % resistance against a challenge with *S. japonicum*, whereas in sheep, vaccination with recombinant FABP reduces the worm burden of a *S. japonicum* challenge infection by 59 %.

Sm23 and Sj23, the integral membrane protein of 23 kDa of *S. mansoni* and ► *S. japonicum*, respectively, is present on the surface of all stages of schistosomes in the mammalian host. It is expressed also by the lung stage which presents a favorable target for a vaccine. Mice vaccinated with its recombinant form or with Sm23 as a multiple antigenic peptide (MAP) achieve 40–60 % protection against a challenge with *S. mansoni* (Table 1). Sm23 administered as plasmid DNA to mice results in a 44 % reduction of worm burden. A similar degree of protection results from vaccination of mice, sheep, or water buffalo with recombinant Sj23 or with plasmid DNA. Interestingly, Sm23 and Sj23 are members of a superfamily of membrane proteins of unknown function expressed by hemopoietic and/or malignant cells of mammals.

Glutathione-S-transferase (GST) is an ubiquitous enzyme that initiates detoxification of xenobiotics or endogenous toxic compounds. Several isoenzymes between 23 and 28 kDa are found in schistosomes and fasciolides. It is localized in the ► *parenchyma* and the ► *tegument* of schistosomula and adult schistosomes as well as of juvenile and adult *F. hepatica*. As much as 70 % reduction in worm burden can be achieved over an extended period in vaccinated sheep and

cattle challenged with *F. hepatica* (Table 1). Protection against a challenge with *S. mansoni* by vaccination with native or recombinant GST reaches levels of 30–60 % in experimental rodents and of 40 % in nonhuman primate models. In addition, it reduces the fecundity of female schistosomes as well as egg viability. As a result, GST may also reduce morbidity and affect transmission efficiency. SmGST28 of *S. mansoni* has been tested extensively and in diverse vaccine formulations. SjGST26 of *S. japonicum* and SbGST28 of *S. bovis* are similarly promising vaccine candidates and have been tested in recombinant form or as plasmid DNA in a variety of hosts. Preclinical trials in people using recombinant ShGST28 of *S. haematobium* have been initiated to evaluate safety. Although no protection data are yet available for mice vaccinated with purified plasmid DNA encoding SmGST28, studies on this DNA vaccine indicate that it effectively stimulates antigen-specific humoral and cell-mediated immune responses.

Triosephosphate isomerase (TPI) is an ubiquitous glycolytic enzyme of 28 kDa that has been detected in all stages of schistosomes. It appears to be localized on the surface of ► *cercariae* and young schistosomula. Monoclonal antibodies specific for TPI confer protection in the murine model and initiated research on this vaccine candidate. Vaccination with synthetic peptides of TPI in the form of MAPs reduces the worm burden of a challenge infection with *S. mansoni* in mice by 30–60 % (Table 1). In pigs vaccinated with a TPI plasmid DNA vaccine, worm burden is reduced by 48 % upon challenge infection with *S. japonicum*. In addition, the egg output is halved, reducing the transmission efficiency of this zoonosis.

Cathepsin L includes two proteolytic enzymes of 27 (CatL1) and 29 (CatL2) kDa that are secreted in the gastrodermis of *F. hepatica* to aid digestion of ingested liver and blood tissue. Regurgitating worms release these enzymes into the host's blood stream. Both cathepsins may also have extracorporeal functions. CatL1 is able to cleave immunoglobulins and may, thus, prevent antibody-mediated attachment of effector cells. CatL2 cleaves fibrinogen furthering clot formation on the parasite's surface. Vaccination of cattle

Vaccination Against Platyhelminthes, Table 1 Candidate vaccine antigens that reduce worm burden resulting from various platyhelminth infections

Vaccine candidate	Molecular mass (kDa)	Form of antigen	Kind of platyhelminth	Kind of host	% Reduction in worm burden
Fatty acid-binding protein	12	Native	<i>Fasciola hepatica</i>	Mice	80–100

Hemoprotein	>200	Native	<i>Fasciola hepatica</i>	Cattle	43

with aTL1 reduces the worm burden of a challenge infection with *F. hepatica* by about 50 % (Table 1). A combination of CatL2 and hemoprotein (see below) achieves more than 70 % protection against *F. hepatica* in cattle. In addition, the egg output of *F. hepatica* in vaccinated sheep and cattle is reduced by up to 70 % and surviving eggs are less viable than those generated in nonvaccinated hosts. In schistosomes, **cathepsin B** and **hemoglobinase** with a molecular mass of 31 and 32 kDa, respectively, are secreted in a similar fashion by those stages of schistosomes that digest blood. Although the protective capacity of these digestive enzymes has not been studied in animals challenged by blood ► **flukes**, related enzymes appear to protect hosts against ► **liver flukes**.

The cestode-specific **45W antigen** has been isolated from oncospheres of *Taenia ovis*. Its recombinant form induces 94 % protection in sheep (Table 1). 45W is the first vaccine against a platyhelminth that is registered for commercial use. However, the amount of 45W expressed by different parasite isolates varies, possibly affecting their susceptibility to anti-45W immune responses. Studies on the oncosphere antigens EG95 of *Echinococcus granulosus* and EM95 of *E. multilocularis* demonstrate similarly high degrees of protection. Oncosphere antigens of taeniid cestodes are promising candidates for the vaccination of intermediate hosts, thereby limiting the transmission of these ► **tapeworms** to their definitive hosts.

The large subunit of **calpain** of 80 kDa, a calcium-dependent neutral cysteine protease,

appears to be secreted by migrating cercariae and schistosomula. Vaccination of mice with recombinant calpain or with a calpain DNA plasmid results in 30–40 % protection in mice against challenge infection with either *S. mansoni* or *S. japonicum*. Fecundity of the adult worms in vaccinated mice is also impaired.

► **Paramyosin**, known to be involved in the catch mechanism of mollusks, is a major component of the thick filament of invertebrate muscles. This 97 kDa protein is expressed by all stages of schistosomes, localized in membrane-bound elongate bodies of the tegument. Paramyosin does not appear to be a surface protein that is easily accessible by the immune system. However, metacercariae of ► *Taenia solium* and adult schistosomes secrete this protein, as it is detected in culture supernatants. Electron microscopy studies also suggest that schistosomula release paramyosin from their postacetabular glands, while shedding the highly immunogenic ► **glycocalyx** of their previous stage. Paramyosin of these platyhelminths inhibits the classical complement cascade by binding to the collagen-like region of C1. As a result, it may modulate the host's immune system. Native and recombinant paramyosin confer protection against challenge infection; at least 30 % reduction of worm burden has been measured in paramyosin-vaccinated mice after challenge with *S. mansoni* and as much as 80 % protection has been achieved against *S. japonicum* (Table 1). Intramuscular injection of a plasmid construct containing a fragment of *T. solium* paramyosin confers 48 % protection in mice challenged with *T. crassiceps*.

Although the **hemoglobin-like protein** found in *Fasciola* has a similar adsorption spectrum to that of hemoglobins, its sequence bears no resemblance to this ubiquitous protein. The function of hemoprotein with a molecular mass exceeding 200 kDa is unknown but may involve oxygen transport or storage. Cattle vaccinated with hemoprotein and challenged by *F. hepatica* harbor a worm burden that is reduced by about 40 % (Table 1). A combination of hemoprotein and cathepsin L achieves up to 70 % protection with an additional 98 % decrease in egg production. Thus, a combined vaccine including hemoprotein may offer the added benefit of limiting parasite transmission.

Parasite-Specific Antigens and Ubiquitous Proteins

The platyhelminth antigens that are currently under investigation as vaccine candidates can be divided into those that are specific to the parasite and those that are similar to host proteins. Parasite proteins of genetically conserved nature bear the risk of stimulating autoimmune responses in the host. Of the vaccine candidates that resemble host proteins, such as GST, TPI, Sm23, cathepsin, and FABP, none has yet been shown to elicit autoimmune responses of the host. Not surprisingly, the epitopes that stimulate protective immune responses are located in the nonconserved, parasite-specific regions of these proteins. If selected epitopes, e.g., in the form of synthetic peptides, are used for vaccination rather than the entire protein, the genetic variability of the host may affect the effectiveness of the vaccine in different host individuals. Parasite-specific proteins such as the hemoprotein of *Fasciola* and the 45W oncosphere protein of *Taenia* constitute unique targets. Their functions remain unidentified, but may relate to the unique requirements of these parasites in their host organisms. Paramyosin, a protein common to invertebrates, may have a different function in platyhelminths, as its location in the parasite suggests. To circumvent the genetic variability of the host organism, a cocktail of a variety of vaccine antigens or of selected epitopes seems most appropriate.

Homologous and Cross-Protective Antigens

Particular vaccine candidates have been identified for several different platyhelminths. GST is a protective antigen in fascioliasis as well as in schistosomiasis, its immunoreactive epitopes, however, differ. Variances in B- and T- cell repertoires of the respective definitive hosts may have led to this distinct immunoreactivity. Within the genus of *Schistosoma*, cross-protection by vaccination with GST may be feasible. Paramyosin secreted by schistosomes and taeniid cestodes may share a similar immunomodulating function for both groups of worms. Some of these homologous antigens even cross-protect their hosts against diverse worms. A particular protein fraction of *F. hepatica* not only protects mice and cattle against the worms that served as source for the antigen preparation, it also reduces the worm burden of mice challenged by schistosomes. This cross-protective protein fraction of liver flukes contains an FABP that is homologous to its counterpart in blood flukes. Similarly, vaccination with the recombinant FABP of *S. mansoni* reduces the worm burden of mice challenged by cercariae by 67 % and completely abrogates the establishment of *F. hepatica* metacercariae in the same animal model. Thus, one antigen may potentially protect against two kinds of worms.

Vaccination Methods

An array of different vaccination methods has been evaluated for potential antiplatyhelminth vaccines. Exposing hosts to **irradiated larvae** consistently generates high degrees of protection. In schistosomiasis, the worm burden of challenge infection in mice vaccinated with irradiated cercariae is reduced by an unsurpassed 90 % compared to nonvaccinated mice. Because it is not practical to vaccinate people or animals with such short-lived attenuated larvae, this approach is considered as a model system to identify vaccine candidates and understand the requirements for optimal vaccination routes (“► **Schistosomiasis, Man**/► **Vaccination**”). **Native antigens** purified from the parasites are usually obtained in such small quantities that they are not sufficient for

more than the early phase of the development of a vaccine. Commonly, vaccine candidates are produced as **recombinant proteins**. Large quantities can easily be generated. Different expression systems are available and the optimal system has to be determined for each vaccine candidate. Recombinant proteins expressed in bacteria however often lack glycosylation sites that are characteristic for the native protein and may, thus, stimulate altered immune responses. Alternatively synthetic peptides that contain protective epitopes may be presented as MAPs. This structure consisting of multiple peptides combined with a branching lysine core is large enough to eliminate the requirement of a carrier. Recently, vaccination with MAPs of TPI and Sm23 in mice challenged with *S. mansoni* produced promising results. The most recent development in vaccinology is the application of **DNA vaccines**. Instead of vaccinating with a protein, its coding DNA is injected into the organism that is to be immunized. The cell machinery of the vaccinated organism subsequently transcribes and expresses the antigen. Compared to protein vaccines, the advantages of DNA vaccines lie in fast and economic production and relative stability for storage. This technology permits multiantigen vaccines. In addition, the protective capacity of heterologous prime–boost vaccinations may be evaluated by priming with a DNA vaccine and boosting with its recombinant protein. Co-injection with particular cytokine-encoding plasmids helps driving the vaccine-related immune response toward protective Th subsets. Such plasmids function as genetic adjuvant, conventional adjuvants are not required.

To increase the immunogenicity of an antigen, various adjuvants are available. Freund's adjuvant, an oil emulsion of heat-killed *Mycobacterium tuberculosis*, saponins, and various other formulations have commonly been used in experimental animal models. Because of possibly severe local and systemic reactions, they are considered unsafe for use in people and their use in animals is now restricted. Solely aluminum hydroxides and aluminum phosphate are registered for use in people. The efficacy of self-replicating live vaccine vehicles is currently being tested; nonvirulent strains of *Salmonella*

typhimurium, *Escherichia coli*, *Bacillus Calmette Guérin* (BCG), or vaccinia virus are transformed with gene fragments encoding the antigen in question. Other antigen vehicles in form of liposomes and proteosomes are similarly under development. Immune-stimulating complexes (iscoms) are cage-like structures consisting of the saponin Quil A, cholesterol, phospholipids, and antigen. Lastly, coadministration of interleukin-12 (IL-12) augments vaccine-induced immune responses to various pathogens. Besides determining the suitable antigen or cocktail of antigens, it is important to determine the optimal carrier for presenting it to the host's immune system.

Vaccination Against Protozoa

³Centro de Pesquisas em Medicina Tropical, Secretaria de Saúde do Estado de Rondônia, Rondônia, Brasil

General Information

Parasite-induced diseases, both in animals and in man, represent a considerable medical and economical burden in many countries. Despite the availability of a number of effective drugs for treatment of the most important diseases, a pressing need for development of successful vaccines remains and is in fact increasing. The reasons for this are multifold. One of the most important is the increasing problem of resistance of vectors and parasites to both successfully used and newly developed drugs. This is typified, for example, by human ► [malaria](#). In animals the main problem is in factory farming, where the presence of parasitic diseases over a long, seasonal time, requires high amounts of antiparasitic drugs, resulting in the associated problems of drug

residues in milk, milk derived products and meat. In addition, such ► [chemoprophylaxis](#) and chemotherapy is often difficult to apply over a long period of time.

Many parasites possess sophisticated ► [immune evasion](#) mechanisms making it, at present, difficult to conceive the development of efficient vaccines. However, the rapid development of immunology and genetic manipulations of cells will perhaps change these perspectives in the near future. Already commercially available vaccines against parasites as well as the state of development of other vaccines which might become applicable for animals or humans in the near future are described in detail under the headwords of the respective diseases.

Immunological Aspects

In general parasites induce a strong humoral and cellular ► [immune response](#) but this does not ensure that the host becomes protected against the disease and also against reinfection. Parasites indeed have developed mechanisms not only to evade immune responses of the host but also to facilitate their survival in the immunocompetent host and their transmission. Therefore, immune responses in most cases do not impair parasites' development and sometimes even favour their development but in contrast often become harmful to the host. Pernicious effect can originate from an excess of activation of the immune system to an exhaustion of the immune system that becomes unable to construct the convenient protective response; also an unbalanced production of cellular and/or humoral effectors can originate that results in immunopathology.

Various evasion/subversion mechanisms have been described among parasitic ► [protozoa](#) to escape the host immunity. Some of them are very sophisticated such as ► [antigenic variation](#), well studied in African trypanosomes and more recently in ► [Plasmodium](#) spp. Antigenic variation depends on polygenic families whose members code for membrane proteins at the surface of the parasite (or the infected cells) and are continuously exchanged. Therefore the immune system

is constantly confronted with new parasite surface molecules. Intracellular protozoa like ► [Leishmania](#), *Toxoplasma* and *T. cruzi* have elaborate strategies to escape destruction by lysosome effectors: avoiding fusion of the ► [parasitophorous vacuole](#) with ► [lysosomes](#) by introduction of parasite proteins in the membrane vacuole like *Toxoplasma*, digesting the parasitophorous vacuolar membrane and invading the cytosolic compartment like *T. cruzi* surface structures which resist complement and hydrolytic lysosome enzymes like *Leishmania*. Invasive ► [Entamoeba histolytica](#) secrete proteases that degrade antibodies and some protozoans inactivate antibodies producing sophisticated papain-like proteases that split the Fab2 fragments in the phenomenon described as fabulation.

Among the various processes elaborated by parasites to escape host immunity, are the production of parasite products able to interfere with the regulation of the immune response: for instance the production of mitogens and or superantigens inducing polyclonal B and/or T lymphocyte activation well described in trypanosomiasis and in toxoplasmosis. In ► [malaria](#) the polyclonal T- and B-cell activation seems rather to be the result of a flood of soluble and insoluble antigens released during the schizonte rupture. The presence in numerous surface antigens of degenerate repeats of amino acids sequences but quite immunogenic is another sophisticated method elaborated by *Plasmodium* to escape immunity. These more or less degenerated repeats are dominant B-cell epitopes, inducing a strong antibody response with large and diffuse affinity avoiding clonal selection and maturation of B cell clones secreting high affinity specific antibodies. Another strategy to avoid the induction of an efficient immune response is the generation of high levels of antigenic polymorphisms. When concurrent presentation to the immune system of different allelic forms occurs, antigenic competition as well as altered peptide ligand antagonism prevent induction of an efficient memory response. This is another ► [evasion](#) strategy utilized by malaria parasites. Another possibility is the production of a dominant antigen subverting the immune system. This is the case of the LACK antigen

(*Leishmania* homologous for activated C kinase) which induces an early secretion of IL-4 by a particular T-cell population, thus creating a micro-environment propitious for the development of a Th2 T-cell response which prevents the development of a healing Th1 response. Some parasites produce macrophage and/or T lymphocyte activators that interfere with the cytokine cascade of the immune response, by an excess production of inflammatory cytokines (TNF, IFN- γ), creating a “cytokine chock” involved in different pathogenic mechanisms like in malaria.

Accomplishments

In the early 1980s, with the development of new technologies in biological sciences, in particular recombinant DNA technology and monoclonal antibodies, it became possible to identify individual antigens that were the target of immune (humoral or/and cellular) responses. It became equally possible to identify, clone, and sequence the corresponding genes and to produce recombinant or synthetic antigens in considerable amounts to study them as possible vaccine candidates against various pathogenic parasites. The field of anti parasite vaccine then attracted a large number of new participants, particularly many brilliant and competent molecular biologists with, however, poor knowledge of parasitology and immunology. Their first contribution was to discover an additional problem for vaccine construction, represented by the extreme variability and plasticity of the parasite genome, concerning sequences coding for potential vaccine targets. At the end of the century, 20 years after the beginning of this golden age, we still do not have any effective subunit anti-parasite vaccine. However, the efforts and investments made by the new generation of “vaccinologists” associated with progress in the understanding of immune mechanisms, has considerably increased our knowledge on the molecular structure of parasites, on the genetic variability, as well as on the immune responses (protective and escape mechanisms) they develop. This will certainly open new alternative pathways

for the development of anti-parasite vaccines. In the present mature status of knowledge in these areas it is reasonable to wait for the birth of recombinant and synthetic vaccines with sufficient effects to be introduced in public health practices for control of parasite infections at the beginning of the new century. In the following, some important progress that has been made in the area since the 1st edition of this book justifying this optimistic view will be summarized.

Progress in Understanding Protective Responses

The efficiency of antibodies in protection against parasites has been shown to depend not only on their inhibition/neutralization activity as observed in virus infections but also on their capacity to interact with immunocompetent cells such as, natural killer cells, monocytes/macrophages, or granulocytes to induce ► ADCC (antibody-dependent cellular cytotoxicity), ADCI (antibody-dependents cellular inhibition), opsonization/phagocytosis, etc. The desired antibody response for such protective mechanisms is, therefore isotype-specific and depend on cellular effectors. New knowledge arises from the role of cytokines, like the role of IL-12 and inflammatory cytokines such as IL-18 and IFN- γ in regulation of the Th1/Th2 pathways of T-helper lymphocytes and in the production of specific cytotoxic CD8 T lymphocytes. Immunologists are accumulating new information on the role of IFN- γ , IL-4, IL13, and IL-10 in the regulation of the immunoglobulin switch in humans.

Progress in Genetics

Considerable progress has been registered in the last decades on protozoan genome structure, particularly in *Leishmania*, ► *Trypanosoma*, *Toxoplasma*, and *Plasmodium* parasites. On the one hand various Genome sequencing programs have now been developed, in particular by US and UK institutions with the support of TDR/WHO and private Foundations. In relation to parasites responsible for human diseases, data banks are organized like the TDR/IMMAL

Malaria DNA sequence database open to access by Internet (<http://www.monash.edu.au/informatics/malaria/who.html>) and the *Leishmania/Trypanosoma cruzi* database. On the other hand, genetic studies of some parasitic protozoa are in progress, due to the success in transfection with navette vectors which are able to grow in *E. coli* and/or yeast as well as in protozoa. These vectors have been used for promoting gene disruption, gene mapping, gene complementation, and gene replacement by homologous recombination. These genetic manipulations allow characterization of target proteins by their function and progress in the understanding of parasite virulence mechanisms as well as new rationale for the construction of attenuated parasites that will replace the empirical ones used so far.

Progress in the Preparation of Antigen Carriers and Adjuvants

Until recently the only allowed adjuvant used in human vaccines was alum (antigens are adsorbed on aluminum hydroxide) which has poor effects. New adjuvants have been investigated and used in human volunteers and in animal trials. ISCOMS (immunostimulating complexes) are large spherical multilamellar structures of the Quil A adjuvant (complex lipid) associated to different immunogens. Other adjuvants in development are DETOX (cell wall skeleton of *Mycobacterium phlei* associated to lipid A and squalen), MPL (lyposome monophosphoril lipid A), mf59 9 (oil-water emulsion), QS-21 (saponin-based adjuvant), and detoxified toxin of *Pseudomonas aeruginosa*, tetanus, and diphteria toxoid. Enhancement of immune responses has also been achieved using cytokines as adjuvants, in particular IL-1 and IL-12, which act by enhancing antigen presentation and/or processing via MHC pathways. In addition to adjuvants, synthetic peptides usually require carrier molecules containing "universal T cell epitopes" able to induce Th cells in a genetically diverse population. Tetanus and diphteria toxoids have been currently used as carriers but provoked some undesirable side effects such as hypersensitive reaction. More recently,

synthetic carriers have been constructed such as MAPS (multiple antigen presentation) composed of 4, 8, or 16 peptide-antigen branched on a lysine core.

DNA Vaccines

Finally, an important biotechnological development represented by DNA vaccines has been intensively studied recently and seems promising. This approach has been successfully used in the immunization of experimental animals against a range of infectious and parasitic diseases as well as several tumor model diseases. The technique involves insertion of the gene encoding the antigen of choice into a bacterial plasmid and intramuscular or subcutaneous injection into the host. This leads to the constant production at a low level of the antigen inducing long-lived humoral and cellular immune responses. Among the numerous advantages of this revolutionary approach over the conventional vaccines is the induction of antigen-specific protective cytotoxic T-cells as well as humoral immunity. The antigenic specificity of the Cytotoxic T cell response depends in this case on antigens presentation via class II MHC molecules. These advances and the emerging voluminous literature on this subject announce a wide use of this approach for animal vaccines development. At the same time, intense experimental vaccination of non-human primates and current trials with human volunteers indicate that DNA vaccines will certainly constitute the third generation of vaccines. Experiments to clarify and develop safety aspects for human use of DNA vaccine are, however, still not available for a generalized use in human trials.

Vaccine Anticoccidials

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The following anticoccidial subunit vaccine candidates had been successfully tested against *Eimeria* species as proteins and DNA delivery or in a vectored version:

- Apical membrane antigen 1
- Microneme protein 2
- Microneme protein 3
- Immune mapped protein 1
- Lactate dehydrogenase
- Rhomboid-like proteins
- SO7
- TA4

However, none of these successful approaches have progressed into commercially available products (despite 30 years of research).

Vaccines

Name

Latin: *vacca* = cow.
Product to protect against infectious diseases. The number of anti-parasitic vaccines is rather limited (Table 1).

Vaccines, Table 1 Anti-parasitic vaccines commercially produced

Parasite	Host	Type of vaccine
<i>Eimeria</i> spp.	Poultry	Non-attenuated
<i>Eimeria</i> spp.	Poultry	Attenuated for precocity
<i>Eimeria maxima</i>	Poultry	Subunit vaccine of gametocyte antigen
<i>Toxoplasma gondii</i>	Sheep	Attenuated for truncated life cycle
<i>Neospora caninum</i>	Cattle	Killed tachyzoites
<i>Babesia canis</i>	Dog	Antigens from in vitro culture supernatants
<i>Babesia bovis</i> and <i>Babesia bigemina</i>	Cattle	Attenuated by repeated passage through splenectomized calves
<i>Theileria parva</i>	Cattle	Non-attenuated wild-type parasites
<i>Theileria annulata</i>	Cattle	Attenuated by in vitro culture
<i>Giardia duodenalis</i>	Dogs	Disrupted axenically cultured whole trophozoites
<i>Taenia ovis</i>	Sheep	Recombinant antigen
<i>Dictyocaulus viviparus</i>	Cattle	Irradiated L ₃ larvae
<i>Boophilus microplus</i>	Cattle	Recombinant tick gut antigen

► Amoebae

The species of this genus belong to the order Schizopyrenida and have a similar life cycle like the members of the genera *Naegleria* and *Tetramitus* and may act as opportunistic agents of disease.

Vampire Bats

General Information

In South and Middle America unique bats occur that lick blood after having scratched the skin of sleeping animals and humans with the help of their sharp incisive and long, stylet-like canini which appear vampire-like. The silent night flights of bats, their occurrence in large numbers, the shape of their teeth, and their blood-feeding activity have surely impressed human minds fearing human vampires and introduced these unique vampire bats as chubacabras into Mexican

Vampire Bats, Fig. 1 Teeth of a vampire bat

folkloristic songs. There exist recent species of such vampire bats (*span.* chubracabras), while three others became extinct, prehistorically.

- ► *Desmodus rotundus* is the most common species; it reaches a body length of about 9 cm, a diameter of the wings of 40 cm and a body weight of about 50 g (thus belonging to the medium-sized bats). The skin hairs of these mammals appear grey to brown, while the breast is light brown (Fig. 1).
- ► *Diphylla ecaudata* varies in body length between 7.5 and 9.3 cm, has small rounded ears and the hairs are dark brown at the backside, while light brown at the ventral side. The eyes are rather large.
- *Diaemus youngi* reaches a body length of 8.5 cm and is characterized by dark brown wings with white rims and tips.
- Three other species – *Desmodus archaeodaptes* (Florida), *D. stocki* (Mexico, USA), and *D. draculae* (Venezuela, Brazil) – died out in prehistoric times. The latter bat was named according to Bram Stokers' novel character Count Dracula.

Feeding Behavior and Transmission of Disease

- Vampire bats are active within the night and spend daytime hidden in buildings, under bridges, and in stony caverns – mostly in colonies of 30–300 animals. At night vampire bats look for prey. They fly around close to the ground and touchdown close to a possible blood spender. Then they crawl lightly onto the skin of the sleeping animals from where they may start with a start jump. In general, horses and cattle are bitten in the ears, between the eyes, along the flanks, or in the sexual organs. In pigs they attack nose, ears, and the ventral body, while in man they prefer fingers, nose, ears, lips, and the lateral sides of the neck. Children and young animals are mainly attacked apparently due to their soft skin. Having reached a favorable site on the host, the vampire bat licks a 10–15 mm² space of the skin and excretes saliva. Then the bat cuts off a small piece of the skin and/or scratches a wound of 1–3 mm in diameter. This process is painless and in general the hosts do not notice it. The blood, which is kept fluid by excreted coagulant components of the saliva, is taken up by licking. Depending on the speed of blood flow the feeding takes 8–60 min (~medium 25 min). Such bats may take up to 40 ml blood, which corresponds to 100 % of their own body weight. The feeding is repeated each night and a portion of the blood is given to their own and other progeny. During the feeding process several pathogens may become transmitted:
 - viruses of ► **rabies** (transmission among animals and to man),
 - viruses of hepatitis B (transmission among humans),
 - trypanosomes (transmission among animals) leading to diseases such as ► **Mal de Caderas** in horses or ► **Surra** in many animals hosts.

Rabies is the most prominent problem, since more than 100,000 farm animals die each year in the

USA and Mexico and many humans are affected, too. Furthermore the mechanical transmission of hepatitis B viruses is highly dangerous for people staying outside overnight in the bat biotopes.

Vampire Fish

Synonyms

Candiru fish

General Information

In the Amazonas river and its tributaries so-called Candiru fish are found which live as vampires. They reach a length of about 1 cm and possess 2 hooklike teeth within their mouth ► *Vandellia cirrhosa*, Fig. 1.

Feeding

By cutting the surface of fish, birds, and mammals (including man) their head may enter the skin and start sucking considerable amounts of blood. During drinking/bathing/working on the host in the water small fish stages (~3 mm in length) may enter the urinary bladder, nose, mouth, anus, or vagina of humans and animals. After a few days severe inflammatory reactions occurred, leading (in many cases) to sepsis.

Therapy

The exclusive therapy is the mechanical removal of the stages and the treatment of the infections by antibiotics.

Van Leeuwenhoek Antonie

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Dutch all-round scientist (1632-1723). One of the first users of the light microscope. Described numerous parasites (e.g., *Giardia* sp.) from his own feces.

Vandellia cirrhosa

Species of the fish family Trichomycteridae (comprising over 40 genera with 180 species of small catfish). They are often nearly transparent (Fig. 1) and due to their small size of 5 cm at the maximum they are often called pencil catfish. *V. cirrhosa* and some related species enter occasionally (in the Amazonas region) the urethra, vagina, or anus of bathing or fishing humans. Due to this activity and its bloodsucking at inner walls of the human or animal organs it is named vampire fish, candiru, or carnero by the local population. Host attraction is probably due to ammonia or urea around these persons. Surgical removal is needed.

***Vandellia cirrhosa*, Fig. 1** DR of a *Vandellia cirrhosa*, also named candiru, the intestine of which is filled with blood

Var Gene Family

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This family comprises about 60 genes that encode *Plasmodium falciparum* erythrocyte membrane protein 1 (PfEMP1), which is one of the best characterized parasite proteins on the surface of the host erythrocytes. Each parasite only expresses one var gene at any time.

VAR Glues

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This family of genes is responsible in *Plasmodium falciparum* for the antigenic variation protein along the surface of the infected erythrocyte. These genes (often more than 50) are scattered over most of the malarial chromosomes. Similar genes (called vir genes) exist in *P. vivax* and others (called SICAvir) are described in *P. knowlesi*. The switching rate from one set of antigens to another one is thought to be high; e.g., apparently two percent of *P. falciparum* stages switched to a new antigen in every erythrocytic cycle. Thus the variations seem non-limited.

Varroa destructor (syn. V. jacobsoni)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The genus name was given in honor to the Roman Marcus Terentius Varro who wrote

***Varroa destructor* (syn. *V. jacobsoni*), Fig. 1** Scanning electron micrograph of *V. jacobsoni*; from dorsal

100 years after Jesus Christ a book on bees; Latin: destructor = destroyer.

This ubiquitous ectoparasitic mite of honey bees (*Apis mellifera*) has its origin in Asia, and due to globalization of goods, it was able to invade many countries around the world in such an intensity that it became the primary cause of colony mortality worldwide. The reason for this effect is seen in the active transmission of several viruses, among which the deformed wing virus” seems to be the most important, since due to its presence, the search of food by working bees is intensively blocked. The adult females lay their eggs in the honeycombs. The proto- and deutonymphs of the mite suck hemolymph at the bee larvae, which thus become weak and finally die (Figs. 1 and 2).

Varroa Migration

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Varroa mites – 2000 specimens of which may kill a population of 30,000 honey bees – have their origin in Southeast Asia, where they first described in 1904 in Indonesia. From thereon they were found in 1959 in China, 1961 in India, 1972 in Brazil, 1977 in Germany, 1987 in the USA and Canada, 2000 in New Zealand, and 2007 in Africa, while no reports exist up to now (2014) in Australia.

Varroacidal Compounds

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Stocks of honeybees are often invaded by *Varroa destructor* mites. This leads mostly after a short time to the so-called Colony collapse disorder, which is treated by several compounds. However, only a few products are registered around the world and several of them have a reduced efficacy due to arising resistances (e.g., ApilifeVar[®], ApiGuard[®], Oxivar[®], MiteAway Quick Strips[®]).

VCTs

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Vector control tools, which are based on measurements of the vectorial capacity of an insect or tick population to transmit agents of disease.

Vector

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name: Latin: *vector* = transporter, transmitter. A transmitter of pathogens and parasites (► [Leeches](#), ► [Vampire Bats](#), ► [Insects](#), ► [Ticks](#), ► [Mites](#)); transmission mostly occurs during bloodsucking or contamination of food with cyst stages from feces of infected hosts.

In parasitology, vectors are described as animals, which transmit actively or passively agents of diseases (e.g., prions, viruses, bacteria, fungi, parasites).

- **Competent vector:** This vector becomes infected by an agent of disease, which is able to replicate inside the vector and is finally transmitted to another receptive host.
- **Permissive vector:** This vector is able to transmit several species of agents of diseases, e.g., several *Leishmania* species at the same time.
- **Putative vector:** The capacity of transmission of this vector is not yet definitively proven by experimental transmissions. Only epidemiological and/or molecular evidence is available.

Vector Capacity

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term calculates the efficacy of a given vector to transmit an infectious stage of a parasite, bacterium, or virus. It is measured by the formula

$$V = ma^2.$$

V = vector capacity; m = density of vectors in a given territory; and a = amounts of blood meals of a given vector at humans.

Vector Competence

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes the intrinsic permissiveness of an arthropod species to become infected by a transmissible pathogen (virus, bacterium, parasite), allows the reproduction of this pathogen inside its body, and finally transmits it to another host. This competence may be restricted to a single pathogen (e.g., dengue virus competent transmission in mosquitoes) or may be enlarged to several pathogens (e.g., transmission of ► [Borrelia recurrentis](#), *B. quintana*, and *R. prowazekii* in body lice; ► [Pediculus humanus corporis](#)).

Vector Control Tool

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Method or intervention that allows to reduce the ability of insects or ticks to transmit agents of disease.

Vector Control Tools

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This term describes measurements to reduce the ability of an arthropod vector to transmit agents of diseases.

Vector-Borne Diseases of Cattle

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Livestock animals that stay for long on the meadow are attacked by a broad spectrum of insects and ticks. Thus regular and accidental transmission pathways of numerous agents of diseases have been developed (Table 1).

► [Insects](#) and ► [ticks](#) are able to transmit a broad spectrum of agents of diseases (viruses, bacteria, parasites). Table 1 summarizes some important groups.

Vector-Borne Diseases of Cattle, Table 1 Common and emerging diseases of livestock due to vector-transmitted agents of diseases

Disease	Pathogen	Main vector	Other vectors
Bluetongue disease (BT)	Bluetongue virus (V)	<i>Culicoides</i> species	Tabanids, flies, <i>Stomoxys calcitrans</i>
Besnoitiosis	<i>Besnoitia besnoiti</i> (P)	Tabanids, flies	<i>Stomoxys calcitrans</i>
Bovine theileriosis	<i>Trypanosoma</i> = <i>Megatrypanum theileri</i> (P)	Tabanids, <i>Ixodes ricinus</i>	<i>Stomoxys calcitrans</i>
Bovine parafilariosis	<i>Parafilaria bovicola</i> (N)	<i>Musca autumnalis</i>	Tabanids
Bovine thelaziosis	<i>Thelazia</i> species (N)	<i>Musca autumnalis</i>	Tabanids
Mastitis	Anaerobes (B)	<i>Hydrotaea irritans</i>	Tabanids, <i>Musca</i> species
Pink eye	<i>Moraxella bovis</i> (B)	<i>Musca autumnalis</i>	Other flies, Tabanids

B Bacteria, N nematodes, P protozoa, V viruses

Vectorial Transmission of Agents of Diseases, Table 1 Transmission speed

Agents of disease	Type of agent	Disease/symptoms	Vectors	Infection time	Therapy ^a
<i>Anaplasma</i> sp. <i>phagocytophilum</i>	R	Anaplasmosis, reduced activity	<i>Ixodes ricinus</i>	24 h	Doxycyclin, Imidocarb

Vesicle Trafficking

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Sporozoites and merozoites (motile stages of coccidian species) are formed at the periphery of sporonts, respectively of schizonts (meronts). Schrèvel et al. (2007) demonstrated the formation of the sporozoites of the malarial parasite *Plasmodium berghei*. Their findings elucidated a process during which an intense vesicle traffic occurs

Vesicle Trafficking, Fig. 1 Diagrammatic representation in five steps of the biogenesis of the organelles at the anterior cell pole of the sporozoites of *Plasmodium berghei* by vesicle trafficking according to Schrével et al. (2007). This diagram may be the blueprint for the same process in other coccidian species. At the bud surface of the oocyst (at the outer side of the intestine of the mosquito), the inner membrane complex (IM) and the plasma membrane form a three-membraned pellicle, underlain by microtubules. The pathway from the ER to the Golgi complex (G) is conserved throughout the sequence during which the nucleus migrates into the bud. The biogenesis of a series of rhoptries (R) in each bud is shown to entail the formation of post-Golgi vesicles and their movement to their points of fusion with the rhoptry base and neck along the rootlet fiber (RF) connected basally to the spindle pole body (SP). After this micronemes (M) begin to be formed by budding from the Golgi complex or spheroidal promicronemes

(MA), which elongate into mature bottle-shaped micronemes (M). These micronemes are finally moved and placed at the apical pole by interaction with subpellicular microtubules (ST). In the final stage of the budding sporozoite, other structures occur including a micropore (MP) and vacuoles (VM). At the base of the budding sporozoite, a constriction ring appears, where the mature sporozoites finally detach from the oocyst's (sporoplasm's) surface. During the final phase the rootlet (RF) disappears. CO coated vesicle, D dense vacuole, ER endoplasmic reticulum, G Golgi apparatus, H half spindle, II invagination of IM, IM inner membrane complex, M micronemes, MA promicronemes, MP micropore, MT microtubule, N nucleus, P polar rings, PM plasma membrane, RA rhoptry anlage, RF rootlet fiber, RI ribosomes, SP spindle pole body, ST subpellicular microtubules, TG trans-Golgi vesicles, V vesicle, VM vesicles deriving from micropore (image: Schrével)

during the formation of the sporozoites when protruding at the surface of the sporont (Fig. 1). This process seems so basic that it probably occurs at least in a similar (if not identical) manner during all budding processes in ► [coccidia](#).

Virchow, Rudolf Ludwig (1821–1902)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

German physician, professor in Berlin for cell pathology and politician (e.g., founder of the Liberal-Democratic Progress Party and member of the German parliament (Reichstag). In the field of medical parasitology, he published renowned papers on the life cycles and transmission of ► *Trichinella spiralis* and several tapeworms. As consequences of these insights, he initiated laws for obligatory meat inspection in Germany (Prussia) that became models for the modern food-control practice of our days. His research results on other fields (e.g., on cell pathology) led to his conclusion – Latin: “*omnis cellula ex cellula*” – thus finishing the scientific discussion on the origin of animals. Although he was very progressive looking at social and practical problems of human life, he remained very conservative with respect to the new fields of bacteriology (based on the findings of ► Robert Koch) and versus the increasing spread of the Darwinism in the scientific community.

Virulence

Although various definitions of virulence were given by different authors, ecologists generally agree that “virulence” is the loss of fitness (reproductive success) of a host due to a parasite (which may be a bacteria, a protozoan, or a metazoan as well as a “virus”).

Evolutionary Aspects

For a long time, it has been believed that, during the course of evolution, virulence evolved necessarily from high to low degree, from war to pacific coexistence. It was then supposed that a well-adapted parasite could only be moderately pathogenic, because it would want its host to survive. For instance, during the nineteenth century, Van Beneden supposed that “the parasite practices the precept: not to kill the fowl in order to get the eggs.” However, several authors have demonstrated that the question is more complex. Ewald summarizes the question as follows: “natural selection does not necessarily favor peaceful coexistence.” As early as 1941, Ball had stated: “a parasite may choose the course of manifest destiny and find aggressiveness more attractive and more valuable than an existence of peace.”

What can be expected is that there exists an optimal pathogenicity, which is a compromise between the benefits and costs of virulence. The optimal pathogenicity is the point at which, as Ebert and Herre point out, “a decrease or increase in virulence is associated with a loss of fitness” (Fig. 1).

Virulence, Fig. 1 Optimal virulence: when virulence is under- or over-optimal, selective pressures cause it to increase or decrease, respectively

Optimal pathogenicity is at the crossroads of two selective processes (called arms races) the “encounter arms race” and the “compatibility arms race.” For various reasons, optimal pathogenicity is not always selected. A maladaptation, which implies that the fitness of the parasite could be improved but is not, may subsist, for instance when the parasite exploits several host species.

Probably the most important point is that the equilibrium between the parasite and its host is fragile. The selective processes which lead to this equilibrium are meaningful only in definite ► [environmental conditions](#). If these conditions are modified, the change often favors the parasite more than the host, because the generation time is shorter and the genetic variation is greater on the side of the parasite, which gives it more opportunities for adaptation. As a rule, parasites (especially microparasites) adapt more rapidly to environmental changes than to their hosts. This accounts for the outbursts of certain human parasites during the course of history and at the present time. The development of medicine has reversed the process: the present-day achievements in drugs and vaccines give increasing advantages to the host, at least to a certain extent.

Benefits and costs

Because the host is both the habitat and the resource base of the parasite, there is a limit in virulence that the parasite should not transgress: beyond this limit (known as optimal virulence, see above), the fitness of the parasite is reduced because the benefit of virulence (exploiting the host so that it can produce its own offspring) is outweighed by the price paid (weakening or killing the host in such a way that the transmission rate decreases or is interrupted). It is only in particular cases that there is virtually no cost of virulence, for instance when the death of the host is necessary for transmission, as in certain life cycles in which a parasite is transmitted from a prey to a predator. In this type of cycle, it is in the interests

of the parasite to be highly virulent, in order to weaken its host so that it can be easily captured by a predator (Favorisation). “Useless virulence” also exists, i.e., a pathogenic effect which has only disadvantages for both the host and the parasite; useless virulence is normally reduced by natural selection.

Visceral Larva Migrants, Man

Synonyms

Toxocariasis; VLM

Pathology

► *Toxocara canis* (from dogs) and other larval parasites such as *Baylisascaris procyonis* (from racoons) or ► *T. cati* (from cats) can cause the visceral ► larva migrans syndrome (VLM) of humans. Since they cannot complete their development in man they are usually not found as adults in the intestine. Instead the larvae undergo a prolonged migration through various tissues of the human host (“► Pathology,” Fig. 28C) with less tropism towards the lung than in the normal host. Most of the nonspecific symptoms of VLM like fever, cough, and ► abdominal pain or signs such as hepatosplenomegaly, lymphadenopathy, granuloma formation, and ► eosinophilia can be attributed to the migrating larvae and the ► host response to them.

The larvae ultimately die in various organs, and each one gives rise to a granuloma, with inflammation containing lymphocyte and eosinophils. Blood eosinophilia is common. Heavy infection such as in children with a craving for pica, the eating of dirt, may lead to myocarditis, ► encephalitis, and granulomas in liver (“► Pathology,” Fig. 28) and lung, together with diffuse inflammation, and is sometimes fatal. Even in light infections, if a larva enters the eye the intense allergic inflammation may give rise to retinal necrosis with formation of granulomas and retinochoroiditis, vitritis, and iridocyclitis. The eye may become blind or be enucleated to exclude a malignant neoplasm, retinoblastoma.

Immune Responses

When laboratory mice are infected with *T. canis* eggs, the larvae disseminate throughout the body and become encapsulated within eosinophil-rich granulomas. A significant peripheral eosinophilia which peaks around day 14 p.i. persists for months thereafter. Both the formation of granulomas and the eosinophilia as well as the IgE and IgG1 antibody responses observed in

experimental toxocariasis are largely CD4⁺ T cell-dependent. Granulomatous reactions which can be found in the musculature, the liver, the kidneys and the heart, begin as accumulations of eosinophils around the worms, and within a week or 2 these cells are replaced by lymphocytes and macrophages. As late as 6 months p.i. the granulomas have contracted in size and the macrophages have become epitheloid, which is suggestive of a response to the secretion of soluble antigens by viable larvae.

The CD4⁺ T cell response against ► *Toxocara* in mice is dominated by Th2 cells. In mice treated with antibodies against IL-5 the pulmonary infiltrates were devoid of eosinophils, while treatment with anti-IFN- γ had no effects on the extent or cellular compositions of the pulmonary infiltrates. In line with this, human T-cell clones with specificity for *T. canis* consistently produced the Th2 cytokines IL-4 and IL-5 in response to *Toxocara* antigens. However, other cells than CD4⁺ T cells might contribute to the production of IL-5. In T-cell-deficient mice the first wave of eosinophilia, occurring at day 11 p.i. could still be detected, while only the second wave around day 21, was absent. Interestingly, it has been reported recently that a population of double negative (CD4⁻ CD8⁻) cells can also produce IL-5.

The functional role of eosinophils, one of the most striking features of tissue-invasive worm parasites, is still a matter of debate. Several studies suggest that eosinophils with their low affinity receptors for IgE (CD23) are highly efficient antiparasitic killer cells. The mechanism of killing is presumed to involve the attachment of the eosinophil via CD23 to the worm which had been opsonized or coated with parasite-specific IgE. The eosinophils then degranulate and exocytose their toxic proteins onto the parasite's surface. However, some findings also suggest that eosinophils may not directly kill *T. canis*. First, in contrast to human eosinophils no CD23 has been detected on the surface of mouse eosinophils. Second, although eosinophils could attach to *T. canis* larvae in vitro, the larval surface was shed and the worms were not affected by this

interaction. Furthermore, in vivo the *T. canis* larvae obviously survive in the paratenic hosts despite a strong infiltration of eosinophils surrounding them in the tissues.

The question as to whether or not a ► **paratenic host** can develop resistance to *T. canis* infection was analyzed in the mouse model in 1960. There was an only partial resistance induced by a primary infection which resulted in approximately 20 % fewer worms recovered from multiply infected mice than from mice infected only once. More interestingly, the worms comprising the subsequent infective doses tended to accumulate in eosinophil-rich granulomatous reactions in the liver, a phenomenon which has been termed “liver trapping.” It appeared to be antigen-specific as mice immunized with secreted products of *Toxocara* did ► **trap** larvae, while mice immunized with the soluble egg antigens derived from *S. mansoni* failed to do so. Anti-IL-5 treatment depleting eosinophils or passive transfer of immune sera from primed mice did not influence the liver trapping. In contrast, the trapping phenomenon was clearly T-cell-dependent because nude mice failed to trap larvae upon a second exposure. Since depletion of CD4⁺ T cells did not completely abrogate liver trapping this host response most likely is a multifaceted reaction.

Wallace Alfred Russel

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

He was a British all-rounder: explorer, geographer, anthropologist, and biologist, who discovered independently from Charles ► [Darwin](#) the basics of evolution of living organisms during his various expeditions to the ancient forests of the archipels of Malaysia and Indonesia (1854–1862).

His article summarizing his observations on evolutionary processes in nature – sent 1858 to Darwin – drove Darwin to finish his ideas, which he had displaced due to his doubts and being torn between his believe as Anglican parson and his insights as scientist. A common publication (Darwin and Wallace) in the year 1858 described

roughly the key stones of the evolution theory later called Darwinism. Although this article contained already all breaking points to the officially accepted divine creation this article did not get public attention. The “storm” of aggression blew up only when the Darwin’s book *On the origin of species* appeared in the year 1859. Wallace was lifelong Darwin’s faithful defender and always stood in the second row, although he really was the kick-off-man of the publication of the evolution theory. Wallace contributed besides his activity a great work to zoography. His book *The geographical distribution of animals* (published in 1876) was the base for nearly hundred years, while his other book *Island life* (published 1881) gave rise to the nomination of the so-called Wallace-line, which represents the borderline between Asian and Australian species.

Wall-Forming Bodies

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This genus belongs to the family Trypanosomatidae and comprises only animal parasite species.

Parasites that produce walled cysts, such as *Pneumocystis*, *Blastocystis*, ► *Amoebae*, *Giardia*, most coccidians, *Balantidium*, ► *Myxozoa*, and

Wall-Forming Bodies,

Fig. 1 DR of a mature eimerian ► *macrogamete* (limited by 2 membranes, other species have only 1). *AM* amylopectin, *DI* dense inclusion, *DWI* developing wall-forming body of type 1, *ER* endoplasmic reticulum, *FN* finger-like protrusion of the active nucleus, *GO* ► *Golgi apparatus*, *HC* host cell, *HN* host cell nucleus, *I* inclusion in ► *mitochondria*, *IF* intravacuolar folds, *IT* intravacuolar tubules, *LM* limiting membranes of the macrogamete, *LP* limiting membrane of PV, *MI* mitochondrion, *MP* micropore, *N* nucleus, *NU* ► *nucleolus*, *PV* ► *parasitophorous vacuole*, *ST* structures surrounding the active nucleus, *UL* underlying material, *V* vacuole, *WF I, II* wall-forming bodies of types I and II

Wall-Forming Bodies, Fig. 2 Diagrammatic representation of an *Eimeria* oocyst, the wall of which is formed by fusion of the wall-forming bodies 1 and 2 (WF I and II in Fig. 1)

► *Microspora*, develop wall-forming bodies of various types (► [Cyst Wall](#)). In amoebae, diplomonadids, *Microspora*, and Myxozoa, the contents of the wall-forming bodies fuse outside the ► [cell membrane](#) after being excreted by ► [exocytosis](#). This fused material forms an external cyst wall. In macrogametes of coccidians, however, the wall-forming bodies fuse in the region immediately below the cell membrane, thus producing an internal cyst wall (Figs. 1 and 2).

One or two different types of wall-forming body may occur in ► [coccidia](#) of the various genera. For example, in ► *Eimeria* and ► *Isospora*, the macrogametes have 2 types of wall-forming bodies: (1) electron-dense bodies that give rise to the outer layer of the ► [oocyst](#) wall and (2) spongelike bodies that fuse to produce the inner layer of the oocyst wall (Fig. 1). The entire oocyst wall is produced inside the cell membrane. The oocysts of ► *Sarcocystis* and the sporocysts of all coccidia are bound by a smooth wall that is formed by the fusion of a single type of electron-dense wall-forming body (► [Cyst Wall](#)/Fig. 2).

Waterborne Infections

Infections due to parasitic stages within water, e.g.,

1. by oral uptake of cysts or eggs: *Cryptosporidium*, *Giardia*, ► [Worm eggs](#),
2. by skin penetration of worm larvae: *Schistosoma* cercariae,
3. by entering nose: *Naegleria*-amoebae, ► [leeches](#),
4. by entering body openings: ► [Vampire fish](#).

Waterborne Outbreaks of Protozoan Diseases

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This term describes smaller or large epidemics due to cyst-forming intestinal protozoans, which are excreted via feces and are transmitted by oral uptake of contaminated drinking water. These worldwide-occurring events are probably very

common, so that the reported 199 epidemics during the years 2004–2010 are probably only the “tip of the ice block.” Interestingly most of the documented epidemics (46.7 %) occurred in Australia, 30.6 % in North America and only 16.5 % in Europe. Most common were outbreaks due to *Cryptosporidium* species (60.3 %) and *Giardia lamblia* (35.2 %).

Watsonius watsoni

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

This species was named honoring its discoverer Watson.

Geographic Distribution/Epidemiology

Focally in Europe, Africa, Asia; relative few humans are infected.

Morphology/Life Cycle

These digenetic trematodes appear pear shaped and reach a size of 8–10 mm × 4–5 mm and thickness of 3–4 mm. Their ventral sucker is located at the posterior pole of their body and thus are placed into the family Paramphistomatidae (see ► [Trematodes](#), ► [Digenea](#), ► *Paramphistomum cervi*). The flukes apparently parasitize in the small intestine. The eggs measure 125 × 75 µm and the miracidia

enter snails of the genera *Bulinus* and *Stagnicola*. The cercariae attach themselves at water plants and become ensheathed to metacercariae, which are infectious for the final hosts (apparently ruminants and humans).

Symptoms of Disease (Watsoniasis)

Infected humans have shown severe diarrheas, abdominal pain.

Diagnosis Until Therapy

Similar to the criteria typical for ► [Fasciolopsis buski](#).

Further Reading

Mas-Coma S et al (2005) Fascioliasis and other plant-borne trematode zoonoses. *Int J Parasitol* 35:1255–1278

Watsonius watsonius

Synonyms

Watsonius watsoni

Classification

Species of the trematode superfamily Paramphistomoidea (► [Digenea](#)).

General Information

This trematode worm species, which is found focally in Europe, Africa, and Asia in the intestine of humans has a pear-shaped body, reaches a length of 8–10 mm, a width of 4–5 mm, and a thickness of 4 mm. The eggs are in size and shape similar to those of *Fasciola*. The infection of humans occurs by oral uptake of metacercariae being attached at water plants.

Disease

Intensive diarrhoea, abdominal pain in cases of heavy infections.

Wedlia

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of the trematode family ► [Didymozoonidae](#) parasitizing marine fishes. The female has a very anterior end and a giant bulbous posterior hindbody, at which the tiny male becomes attached. Thus both together look like a sac with two tiny protrusions.

WEEV

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Western equine encephalitis virus. This virus was first found in the western regions of the USA and

leads to an encephalitis in horses and humans. Today this virus is found in western USA, whole Central America, and all central and northern states of South America. It is transmitted by *Culex tarsalis* mosquitoes and may use rabbits/hares as hosts, too.

Weight Loss

Clinical symptom in animals due to parasitic infections (Alimentary System Diseases, ► [Clinical Pathology, Animals](#)).

Weighted Degree Day Value

Mode of measurement of the chances for overwintering/surviving of an agent of disease in a vector. Day maximum temperatures over 18 °C get 6 points, temperatures of 13–17 °C 1–5 points. The points obtained within 1 month are added and finally divided through the number of days of the month. The survival of an agent such as the blue-tongue virus in a certain region is limited by the temperature. This virus can only persist in its hosts, if temperatures below 13 °C occur at less than 40 days in a year at the habitat. Even short periods of freezing will not influence this rule.

Weil's Disease

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This disease (Morbus Weil) which is characterized by the symptoms fever, icterus, hemorrhages, and destruction of kidneys was described in detail in the year 1886 by the German physician Adolf Weil. For long – even after the year 1915, when Japanese and German scientists had isolated

bacteria of the genus *Leptospira* as agents of these symptoms – it was believed that these bacteria are involved in the outbreaks of the so-called ► [yellow](#) fever, since in both cases the patients suffer from icterus, which leads to a yellowish skin. The Morbus Weil is initiated due to infections by serovars of the species *Leptospira interrogans* (e.g., *L. icterohaemorrhagiae*, *L. grippityphosa*, etc.). The transmission occurs by means of a zoonosis, since the urine of rats, pigs, cattle, and dogs may contain these bacteria. Transmission by flies is under discussion and seems very probable.

Weil-Felix Reaction

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Serological method developed by the Austrian bacteriologist **Weil** (1880–1922) to detect rickettsial infections (e.g., those of the spotted fever transmitted by body lice).

Wenyonella

Genus of ► [Coccidia](#) in ducks. The oocysts contain 4 sporozoites in each of the 4 sporocysts, e.g., *W. anatis*.

Werneckiella

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of ► [Mallophaga](#) of horses and other equids (e.g., *Wernieckiella equi equi*, *W. equi*

Werneckiella, Fig. 1 DR of a female mite from dorsal, EI egg

asini, Fig. 1). Both species may lead to itching and loss of hair.

Therapy

Acaricidal Drugs.

West Nile Fever

Virus disease transmitted by ► [Culicidae](#) (► [Togaviridae](#)), recently spreading all over USA.

West Nile Virus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This *Flavivirus* was described first in Uganda (1937) and spread further north in Africa, where

it got its final name. Due to migration in humans, respectively, and/or migrating birds, it is recently propagating in countries with adequate temperatures for the vector (*Aedes* and *Culex* mosquitoes). From Africa it arrived between 1962 and 2000 at places around the Mediterranean Sea. In the year 1999, it arrived at the East Coast of the USA and was diagnosed first in patients suffering from encephalitis. Within 4 years human cases were found all over the USA and led to 2,000–3,000 cases per year with a mortality rate of about 4.5 %. In animals the mortality reaches similar rates.

Wings of Diptera

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The wings of flies show genus-specific patterns, which are formed by the arrangement of different vessels (venation) giving rise to different open or closed “cells.” Especially the shape of the cell R_5 is genus specific (Figs. 1 and 2) as well as that of the disc cell, which is situated on the lower left side of the R_5 cell. Figs. 3, 4, 5, 6, 7, and 8 show micrographs of typical wings.

Winterbottom Sign

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Palpable swelling of the skin of the lateral/posterior region of the neck as first sign of an infection with stages of ► *Trypanosoma brucei rhodesiense* or *T.b. gambiense*. This swelling is the result of the infection of the lymph nodes in this region. This symptoms name honors the English physician Thomas Masterman Winterbottom (1765–1859), who first described this symptom in human cases of trypanosomiasis.

Wohlfartia, Fig. 1 DR of an adult fly

Rickettsia spp. They are obligate intracellular bacteria that are transmitted from female hosts to their eggs. Up to now a total of 8 subgroups (A–H) is described using molecular data (cell cycle protein FTSZ/ftsZ; SSU rRNA). Groups A, B have been found only in arthropods, groups C, D only in filarial nematodes and rarely in insects (lice), while group G occurs in spiders and group H only in the Pacific dampwood termites.

The genus *Wolbachia* represents a group of bacteria that are able (among benefits) to introduce different phenotypic effects on their evertbrate hosts. Their efficacy ranges from initiating the popcorn disease of fruit flies to a possible beneficial effect of group D in filarial worm (► [Filariidae](#)), and from introducing ► [parthenogenesis](#) in wasps to ► [feminization](#) of genetically determined males in crustaceans. Today, studies are being carried out in order to eliminate or disturb the symbiotic effect of *Wolbachia* in filariae. To date these bacteria are described in ► [Acanthocheilonema viteae](#), ► [Brugia malayi](#), *B. pahangi*, *Dipetalonema setariosum*, ► [Dirofilaria immitis](#), *D. repens*, *Litomosoides sigmodontis*, ► [Loa loa](#), *Mansonella ozzardi*, 10 species of ► [Onchocerca](#) including *O. volvulus* and in ► [Wuchereria bancrofti](#). In all cases they were determined in all developmental stages of the filariid life cycle (being especially abundant in adults). *Wolbachia* stages, however, are restricted to the hypodermis and the reproductive tissues (e.g., in the ovary of ► [Glossina](#)), and are thus being included in the eggs. They are situated within a vacuole of their host cell and reproduce therein.

Wolhynic Fever

Disease in humans due to infection with *Rickettsia quintana* transmitted by body ► [lice](#).

Wucherer, Otto (1820–1873)

German physician; after studies in London, he worked in Lissabon and emigrated in 1847 to Bahia (now Salvador). There he discovered in August 1866 the hookworm disease and also (in human urine) the microfilariae of the worm, which is now described by his name (► *Wuchereria*). After a short return to Germany he died in 1873 in Brazil (in absolute poverty).

Wuchereria bancrofti

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

The scientific name of this nematode was given in honor to the scientists Otto Wucherer (1820–1873) and Joseph Bancroft (1836–1884). The trivial names of *W. bancrofti* are filarial worm and lymph filaria.

Worm Larvae, Fig. 2 Light micrograph of an infectious larva 3 of a hookworm

Worm Larvae,

Geographic Distribution/Epidemiology

W. bancrofti inhabit humid-warm regions in Africa, Asia, and South America. It is estimated that about 100 million humans are infected, although apparently only 1 % of the infections lead to adult worms.

Morphology/Life Cycle

The adult worms of this species reach as females a size of 10 cm × 0.3 mm, while males remain considerably smaller (4 cm × 0.1 mm). Several worms live together in the lymphatic vessels and lymph nodes of humans and monkeys and form

Species	<i>Wuchereria bancrofti</i>	<i>Brugia malayi</i>	<i>Loa loa</i>	<i>Mansonella perstans</i>	<i>Mansonella ozzardi</i>
Shape					
posterior end					
anterior end					
size	300 x 8 μm	220 x 6 μm	270 x 8 μm	180 x 4 μm	200 x 4 μm

Worm Larvae, Fig. 4 Diagrammatic representation of the larva of different species of the Filariidae

knots, which block the flowing of the lymph. It takes 1–2 years until the worms reach maturity. After repeated copulations the females produce for 6–7 years sheathed microfilariae (Figs. 1 and 2). Even after they stopped microfilariae, the adults may stay there for up to 20 years. The microfilariae reach a size of 270–320 μm × 8–10 μm, may survive for 6–24 months, and appear rhythmically in the late evening (~10 p.m.) in the peripheral blood vessels, from where they were ingested by nocturnally active mosquitoes of the genera *Anopheles*, *Culex*, and *Aedes*. The microfilariae are therefore called “microfilariae nocturna.” However, there exist also strain variations (e.g., *W. bancrofti* var. *pacifica*), which appear in the afternoon hours within the peripheral blood vessels. In these cases the transmission is done by day-active *Aedes* species. It is not sufficiently clear whether *Wuchereria lewisi* in Brazil is really a separate species. All

developmental stages of the life cycle (e.g., eggs, larvae, adults) are provided with bacteria of the genera *Wolbachia*, which are essential for a successful embryonic development of the larvae inside eggs and during their growth to adults.

Symptoms of Disease

The first symptoms occur mostly only 4–8 months after the infection, so that people coming from endemic regions are not aware of being infected, and therefore, the later occurring symptoms are often not considered. These early symptoms are nonspecific fevers, swellings of lymph nodes (lymphangitis), inner inflammation processes, pain along the legs and arms, and occasionally reduced sensitivity along leg and arm regions. During this early phase of infection, microfilariae are not yet detectable; they may even appear 1–2

Wuchereria, Fig. 1 *Wuchereria* and related species. Life cycles of human filarial worms. **A** ▶ *Loa loa* adult worms (= ▶ *macrofilariae*: male 3.5 cm, female 7 cm) wander subcutaneously and may pass the anterior chamber of the eye (1). **B** ▶ *Wuchereria bancrofti* adults (male 4 cm, female 10 cm) and ▶ *Brugia malayi* adults (male 3 cm, female 9 cm) live in lymph vessels and lead to a late-stage disease called ▶ *elephantiasis tropica*(1). **C** ▶ *Onchocerca volvulus* adults (male 2–4 cm, female 70 cm) are knotted together in groups in the subcutaneous tissues. Because of host reactions these groups are encapsulated, leading to palpable ▶ *nodules* (1). In sections of these nodules coiled adults are seen (1.1). Microfilariae may induce blindness. **1** Visible signs of diseases. **2** Microfilariae; the long-living females produce (after copulation) thousands of first-stage larvae daily, which measure about $260 \times 8 \mu\text{m}$. Their

shape (2.1), structure (2, 2.2), and diurnal occurrence are species-specific: they may or may not be sheathed (2.2); their terminal nuclei have a species-typical appearance (2, 2.2); they can be found in blood vessels (*Loa*, ▶ *Brugia*, ▶ *Wuchereria*) or in lymphatic gaps (▶ *Onchocerca*); their occurrence in the peripheral blood can be periodical (*Loa*, during the day; *Wuchereria*, during the night; some subperiodic strains also exist), or may not be (*Onchocerca*, always present, but in lymph vessels). **3** Intermediate hosts: Depending on the periodic appearance of microfilariae in the host's skin, insects with different biological behavior are involved as vectors. Daytime-feeding vectors (deerflies, ▶ *Chrysops* spp.; ▶ *blackflies*, ▶ *Simulium* spp.) transmit *Loa loa* or *Onchocerca volvulus*, whereas night-feeding ▶ *mosquitoes* (*Aedes*, *Culex* *Anopheles*) may be vectors of the nocturnal strains of

accumulation of cells

Wuchereria, Fig. 1 (continued) *Wuchereria* and *Brugia*. When microfilariae are ingested by the intermediate hosts during the blood meal, they penetrate the intestine and enter the abdominal cavity and the thoracic muscles. After a molt the L_2 is formed, which has a stumpy shape (sausage stage). Another molt finally leads to the filariform infectious L_3 . 4–5 L_3 reach a length of about 1.5 mm and migrate to the ► [proboscis](#), from which they escape when the vector is feeding. They enter the skin through the

wound channel made by the biting insect (5, [arrow](#)). Inside the final host (man) the larvae migrate until they reach their favorite site of location, where they mature (after another 2 molts) within 1 year (prepatent period; ► [Nematodes](#), Table 1). AD adult worms (in section), AN anus, E esophagus, ER erythrocyte, IN intestine, L_3 third-larval stage, N nuclei (their arrangement at the poles of microfilariae is species-specific), SH sheath (Eggshell)

years after the infection. The later following symptoms occur when microfilariae enter the lymphatic vessels and are often characterized by encephalitis syndromes. During this phase lymph blockade, swelling of extremities, and chyluria may occur and will worsen over time. During this phase microfilariae can be diagnosed in the blood. As extreme late reaction, **elephantiasis tropica** may occur and becomes visible by enormous swellings of legs, scrotum, or female breasts.

Diagnosis

This diagnosis is based on the microscopical demonstration of the sheathed microfilariae in the peripheral blood (Fig. 2). Due to the nocturnal appearance, blood investigation should not start earlier than 10 p.m. The blood can be stored until the next morning. The so-called Mazzotti provocation test (oral uptake of 50–100 mg diethylcarbamazine 30–60 min before blood collection) makes it possible to obtain infected peripheral blood also at daytime. However, in cases of cross-infections with *Loa loa* or *Onchocerca volvulus*, severe anaphylactic reactions might be possible. Since microfilariae may occur in low numbers, enrichment methods are often necessary.

The following diagnostic techniques are commonly used:

(a) Membrane filtration:

3–5 ml EDTA or citrate blood is hemolyzed with aqua dest or saponin and is pressed by help of a 10 ml syringe through a polycarbonate filter with 3 µm sized pores. After repeated use of NaCl 0.9 %, the filter is stained with Giemsa solution and studied with a microscope.

(b) Knott's enrichment method:

1–10 ml EDTA blood is mixed with 10–100 ml of 2 % aqueous formalin solution.

After 10 min centrifugation at 1,500 g, the sedimented worms can be diagnosed.

(c) Thick droplet technique and Giemsa stain

The thick droplet technique followed by *▶ Giemsa stain* provides also good results for the detection of a persistent microfilaremia.

(d) Serological methods (e.g., ELISA, IFT)

Serological methods (e.g., ELISA, IFT) give mostly good results, showing heterologous as well as homologous filarial antigens. These techniques are especially useful during the late phase of the disease, where only very few microfilariae are still present.

Infection

The infection occurs due to bites of infected females of the mosquito genera *Aedes*, *Anopheles*, and *Culex*. During their blood meal, the larvae 3 leave the head region of the mosquito and enter the skin via the biting site. During each sucking phase, 4–60 larvae may be transmitted. Infections can be repeated, since immunity is not established.

Prophylaxis

Avoiding bites of mosquitoes in endemic regions is the best protection. This can be done by the use of repellents and by sleeping under insecticide-impregnated mosquito nets.

Incubation Period

Three to eighteen months.

Prepatent Period

Seven to twenty-four months.

Patency

Eight to ten years although adult worms may survive for 18–20 years.

Treatment

Diethylcarbamazine was the drug of choice to control adults and microfilariae. Today treatment with doxycycline has become much more efficient.

Xerodermia

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Name

Greek: *xeros* = dry; *derma* = skin. This symptom of skin disease is characterized by formation of a dry, horny, scaly skin. Besides mild forms of ichthyosis, this clinical picture (xerodermia) can also be introduced by wandering larvae 1 of the filarial worm ► *Onchocerca volvulus*, which is the agent of onchocercosis, onchocerciasis (► [River Blindness](#)).

Xerophil

Species adapted to dryness (e.g., phlebotomes, ► [sand tampan](#)).

Xerophthalmy

Drying of eye as symptom of lack of ► [vitamin A](#).

Xiphidiocercariae

► [Cercariae](#) with apical bore stylet. ► [Digenea](#), ► [Prosthogonimus macrorchis](#).

Xiphidiopsylla Species

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

The eight species of this genus of fleas were described from rodents in highlands of East Africa.

XX-XO Type

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

This abbreviation describes the sex chromosome constellation of many male nematodes. This pattern means that the male has only one sex chromosome (e.g., *Trichuris trichiura*). While the female has in total $2n = 8$ chromosomes, males

of this species possess $2n = 7$ chromosomes. However, males of other species in the same genus may be of the XY type and have two sex chromosomes (e.g., *T. ovis*, which show $2n = 5$). The following species also belong to the XO type: *Contracaecum spiculigerum* ($2n = 16$), *Strongylus edentatus* ($2n = 12$), *Haemonchus contortus* ($2n = 12$), *Ancylostoma caninum* ($2n = 12$), and *Setaria equina* ($2n = 12$).

Also ixodid ticks have developed the XO type, so that the males possess one chromosome less than the females (e.g., *Haemaphysalis sulcata*: ♀ = 22, ♂ = 21). On the other hand, leather ticks are of the XX-XY type, so that both sexes possess always the identical number of chromosomes (e.g., ♀, ♂ of *Ornithodoros gurneyi*: 12; *O. alactagalis*: 34; *Argas* sp.: 26).

XX-XY Type

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This abbreviation describes the sex chromosome situation, when male individuals have a smaller second sex chromosome. This constellation is rather rare in nematodes, which often show the XO situation, where one chromosome is lacking (e.g., *Strongyloides ratti*).

Yellow Fever

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This disease which affects monkeys and humans was first symptomatically described in 1648 in Mexico (Yucatan half island). Its origin, however, is probably Africa and it came to America via slave transportation. The name of the fever refers to the yellow skin of infected people. Today this disease is found in Africa in countries between 15° north and 15° south of the equator,

endangering about 500,000 million humans suffering from increasing infection rates. In South America, the disease is endemic in ten countries with low urban infection rates. In Asia no cases were found until today, although all basic criteria for a successful transmission are present: vector mosquitoes of the genus *Aedes* are present in great numbers as well as the tropical temperatures, low living and medicinal standards.

The agent of the disease is a 40–50 µm wide enveloped RNA-virus, belonging to the name giving Flaviviruses (Latin: *flavus* = yellow, pole). These viruses enter monocytes, macrophages, dendritic cells, and finally hepatocytes after they had attached to the cell surface via specific receptors. Then they are taken up by an endosomal vesicle, whereby the decreased pH initiates the fusion of the endosomal membrane with the envelope of the virus. Thus the capsid reaches the cytosol and releases the genome. Replication of the viral genome occurs in the rough endoplasmic reticulum and is then processed in the Golgi apparatus.

Transmission

Vectors are mosquitoes of the genera *Aedes*, *Haemagogus*, and *Sabethes*, whereby *Aedes aegypti* is the most important species in the so-called “urban cycle”, which includes only humans, while in the jungle (sylvatic), especially the Savannah cycle (only in Africa), mainly nonhuman primates are involved. Replication of the viruses occurs in the epithelial cells of the intestinal tract of the mosquitoes. The viruses finally reach the salivary glands via the fluid in the body cavity and may be transmitted via saliva to the next host.

Symptoms of Disease

After an incubation period of 3–6 days the first phase of the disease is characterized by rather mild symptoms showing fever, headache, chills, back pain, loss of appetite, nausea, vomiting, and general weakness. The second and toxic phase is

reached, when severe symptoms appear such as recurring high fever; jaundice; haemorrhages in mouth, eyes and inner organs; bloody vomiting; eventually shock; failure of multiple organs; and death in high percentages.

Diagnosis

- Anamnesis of case history
- IgG titers
- Specific IgM antibodies
- RT-PCR test to show the virus genome
- Isolation of the virus and culture techniques

Therapy

There is no medication available; however, prevention can be done by vaccination that was first developed by ► [Max Theiler](#) and by use of ► [repellents](#) in order to avoid mosquito bites.

Yellow Fever Vaccine

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The vaccine of the recent status of art is produced in chicken embryo cells, while at the beginning Max Theiler developed in 1937 the so-called 17D-vaccine with the help of mice and monkeys at Rockefeller University. Since this vaccine was an enormous breakthrough in healthcare in the tropical countries of the Americas, (e.g., the

construction of the Panama Channel was stopped for many years due to a yellow fever epidemic.) Theiler received in 1951 the Nobel Prize of Medicine and Physiology for this breakthrough in developing the 17D-vaccine. The modern version of this 17D-vaccine protects (according to WHO statements in 2013) lifelong from symptoms of yellow fever – although boosting all ten years is recommended for travelers.

Yersin, Alexandre Emile Jean (1863–1943)

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Alexandre Yersin was a Swiss-born physician who spent most of his time as a member of the famous Institut Pasteur. In 1888, after he had received his PhD by presentation of research results on tuberculosis, he participated at a course on bacteriology directed by Robert Koch in Berlin (Germany). Starting from 1890, he worked in Indochina as a ship physician. In 1889, he was asked by Emile Roux to lead a course on bacteriology at the recently established Institut Pasteur. In 1894, when the plague epidemic from Mongolia reached the South China coast, the French Government and the Institut Pasteur sent him to Hong Kong, which was a British colony at that time. In a very short time, he succeeded to isolate the agent of the plague disease. Until 1970, this

bacterium was named *Pasteurella pestis*, but was then renamed *Yersinia pestis*, honoring his dangerous, but successful work. His research had been successful, although the local health authorities did not support him, but only Kitasato, who obtained similar results (published in 1894). However, those cultures he photographed contained other bacterial contaminations besides plague bacteria. In 1895, Yersin worked in Paris to develop an antiplague vaccine, which he tested during the pest epidemic in Bombay (India) in the year 1871. However, this test vaccine failed and did not protect patients. From this period on, he worked on different projects in French Indochina and became director of the Institut Pasteur at Saigon and Nha Trang, which he headed from 1904 to 1924. After his return to Europe and Paris, he became a member of the scientific board of the mother institute of the Institut Pasteur at Paris and was elected honorary director.

Yersinia pestis: Discovery of transmission

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The French scientist Paul-Louis Simond (1858–1947) – member of the famous Pasteur Institute at Paris (France) – came into contact with the plague disease, which had threatened and killed as Black Death during several centuries millions of humans, 3 years after Yersin and

Kitasato had discovered the plague bacillus in 1894 – both working simultaneously in Hong Kong (Yersin 1894; Kitasato 1894; Simond et al. 1998; Grüntzig and Mehlhorn 2010a, b). He had been sent to Bombay (India) as successor of Yersin in order to bring an experimental serum into use that had been developed by Yersin at the Pasteur Institute. As this time, the transmission pathway of plague was under intense discussion in the German, English, Russian, Italian, and French scientific communities, and the idea of an activity of arthropods as vectors of pathogens was in its “children’s shoes” or even not yet born. Simond, as an active physician, noted that at the beginning of a plague infection, small blisters occurred on the skin of the patients, containing a fluid with numerous bacilli. He concluded that this blister (phlyctène précoce) should be the infection site, which later becomes the large necrotic buboe (*French*: charbon pesteux). Simond had the idea that this small blister could be due to an insect bite. Thus, he believed that fleas as vectors could be involved in transmission. He studied cockroaches at first and afterward fleas, which were abundant there due to the occurrence of masses of rats in the poor quarters of this overcrowded Indian town. He detected plague bacilli inside the fleas, which he collected from dead rats. At the same time, Kitasato’s colleague Ogata described in 1897 similar findings in fleas in the German language in a German journal, but he missed to draw Simond’s conclusions that fleas are the plague vectors and that therefore rats as hosts of fleas should be kept away from human surroundings. Simond depicted his findings and conclusions in a protocol in the year 1898 and informed thereby director Roux of the Pasteur Institute at Paris, who published the data in the *Pasteur Annales*, so that this idea was spread among scientists without being officially published by Simond in a scientific journal at this early time. However, as it is usual, revolving ideas are hit by skepticism – not only by the home-proud English scene but also by French colleagues. This offense against a flea transmission of plague was kept alive, although there had been several scientific hints on the possible vectorship

of arthropods before Simond’s observations (e.g., Finlay in 1864 discussed mosquitoes as vectors of diseases of – at this time still unknown – viruses of the yellow fever, Manson saw in 1878 relations between mosquitoes and transmission of filarial worms, and Bruce in 1884 described the involvement of tsetse flies in the transmission of trypanosomiasis) (Grüntzig and Mehlhorn 2010a, b). However, after many troubles and after an official publication of Simond in French in the year 1905, two English scientists confirmed finally the vectorship of fleas in the transmission of the plague bacterium that is now called *Yersinia pestis* (Bacot and Martin 1914).

Yersinia pestis

Synonyms

Bacterium pestis or *Pasteurella pestis*.

Agent of plague being transmitted by tropical rat fleas (*Xenopsylla cheopis*, Fleas, Insects, Fig. 7); Yersin, Kitasato.

Yersin-Kitasato Controversy

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

There had been broad discussions whether Yersin alone or both Yersin and Kitasato had detected the agent of plague in the year 1894. David J. Bible and T. H. Chen summarized in the year 1976 the different reasons and facts that may have led to the decision for one or the other person. From our days' view, there were a lot of political reasons that led contemporary scientist to decide for ► [Yersin](#) or ► [Kitasato](#), since at that time the rising powers Germany and Japan started to come in competition with the old big powers France and England. Besides, of all these queries, both scientists – Yersin and Kitasato – did a great

job always being endangered to become fatally infected themselves.

Yolk

Reserve material inside eggs or special cells being added to growing larvae. The so-called yolk cells of ► [Digenea](#) (being formed inside of the ► [vitellarium](#)) give rise to the eggshell.

Z

Zebra Tick

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

See ► [Rhipicephalus](#) species (*R. pulchellus*).

Zibet Cat Fluke

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Trivial name for the trematode *Opisthorchis felineus*.

Ziehl-Neelsen Staining

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Method of demonstrating *Cryptosporidium* oocysts in fecal smears (Figs. 1 and 2).

This technique is today used in parasitology to make visible the extremely tiny oocysts of *Cryptosporidium* species. In bacteriology, this dye is used to stain the bacterial agents of tuberculosis (*Mycobacterium tuberculosis*) and leprosy (*M. leprae*). This method was developed by Franz Ziehl and Friedrich Neelsen when adapting in the years 1882 and 1883 the method of Paul ► [Ehrlich](#), who used crystal violet to stain acid resistant rod-like bacteria. Ziehl added phenol and Neelsen used fuchsin red and their colleague Rindfleisch perfected the method in 1883 by recommending to heat the probes during the coloration process. The process of the Ziehl-Neelsen runs as follows:

Ziehl-Neelsen Staining, Fig. 1 Cryptosporidial oocysts stained according to this method appear *reddish*; in the figure at the *left* side some cysts are colored in different intensities

Ziehl-Neelsen Staining, Fig. 3 *Cryptosporidium* oocysts – unstained after use of a concentration method, which is only useful if these parasites occur in larger numbers

Ziehl-Neelsen Staining, Fig. 2 Cryptosporidial oocyst stained according to this method appears *reddish*;

1. An aqueous fecal smear is spread on a glass slide and left to dry.
2. Then this layer is covered by a solution of phenolfuchsin red.
3. By help of a flame this solution is heated three times.

4. Then the phenolfuchsin is discharged and the slide is entered shortly into tap water.
5. Contraststaining with methylene blue.
6. Acid stable structures appear red on blue background Fig. 3 shows unstained oocysts of *Cryptosporidium* sp.

Ziemann's Dots

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This term describes the appearance of malaria pigment distributed as very fine dots inside erythrocytes infected by *Plasmodium malariae*.

Zika Virus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This virus, which is transmitted, e.g., by *Aedes aegypti* mosquitoes, belongs to the group of Flavivirus and was first described in 1947 in rhesus monkeys in Uganda. Since then, the virus circulates in Africa, the Americas, and the Pacific. During an outbreak especially in Brazil in 2015/2016, it turned out that many cases of microcephaly occurred in unborn and newborn children. Whether this phenomenon is definitively related to an infection with this virus is not yet fully proven, since in general infections showed the following mostly mild signs of disease:

- Mild fever for 2–7 days
- Headache
- Skin rashes
- Conjunctivitis
- Muscle and joint pain
- Malaise.

Zinc Deficiency

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

During malaria patients suffer from zinc deficiency. Thus food addition of zinc besides iron and vitamin A reduces severity of symptoms.

Zoëa

Larva of higher ► [Crustacea](#), characterized by two large compound eyes and many paired extremities (► [Isopoda](#)).

Zoite

Stage within ► [Tissue-cysts](#) of ► [Coccidia](#), may become motile (► [Bradyzoites](#), ► [Tachyzoites](#)).

Zoniolaimus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Genus of nematodes (Strongyloidea) parasitizing in kangaroos in Australia, e.g., *Z. mawsonae*, *Z. latebrosus*.

Further Reading

Huby-Chilton F et al (2002) Redescription of *Zoniolaimus mawsonae*. *Syst Parasitol* 1:81–93

Zonula

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Small region of an organ, e.g., zonula ciliaris = fortifying band at the lens in the eye.

Zooanthroponoses

Synonyms

Anthropozoonoses

Zoogeography

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Zoochory

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *zoon* = animal; *chorizein* = distribute.
Transportation, e.g., of worm eggs by feces
feeders into other biotopes.

This term describes a scientific discipline, the
topics of which are concerned with the geographic
distribution of recent animals (parasites) or those
in the past. The regional distribution e.g. of human
filariae in Africa (e.g., ► *Onchocerca volvulus*,
Loa loa, *Mansonella perstans*, *M. streptocerca*,
Wuchereria bancrofti, and their vectors allow con-
crete mass treatments.

ecology, competitive exclusion, and public health rele-
vance. Trends Parasitol 30:163–169

Zooflagellata

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *zoon* = animal; Latin: *flagellum* = whip.
This term comprises flagellated protozoans,
which are heterotrophic (e.g., they ingest organic
material via cytostomes). Examples are
Protomonadida, Diplomonadida (e.g., *Giardia*),
Polymastigina.

Zoology

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *zoon* = animal; *logos* = knowledge.
Knowledge on animals.

Zoonoses

Diseases due to agents being transmitted between animals and man (► [Anthropozoonoses](#)).

However, there are many diseases affecting only animals. The major representatives of such parasitic “animalosis” are listed in Table 1.

See also ► [Anthropozoonoses](#), ► [Opportunistic Agents](#).

Zoonoses, Table 1 Economically important parasites which are usually restricted to animals other than man. (According to Wernsdorfer)

Parasite species	Principal hosts	Infective stage	Mode of infection	Other obligatory hosts	Disease
Protozoa					
<i>Trypanosoma equiperdum</i>	Equines	Trypanosome	Sexual transmission	None	Dourine
<i>Trypanosoma evansi</i>	Various domestic animals	Metacyclic trypanosome	Bite of horseflies	<i>Tabanus</i> spp.	Surra
<i>Trypanosoma brucei</i>	Bovines, equines, camels, porcines, canines	Metacyclic trypanosome	Bite of <i>Glossina</i>	<i>Glossina</i> spp.	Nagana
<i>Trypanosoma congolense</i>	Bovines and other domestic mammals	Metacyclic trypanosome	Bite of <i>Glossina</i>	<i>Glossina</i> spp.	Bovine trypanosomiasis
<i>Trichomonas gallinae</i>	Avians	Trophozoite	Ingestion	None	Avian trichomoniasis
<i>Tritrichomonas foetus</i>	Cattle	Trophozoite	Sexual transmission	None	<i>Tritrichomonas</i> abortion
<i>Histomonas meleagridis</i>	Avians	Ameboid and flagellate forms	Ingestion	None	Blackhead enterohepatitis
<i>Nosema bombycis</i>	Silkworms	Spore, transovarian and regular forms)	Ingestion, transovarial	None	Pébrine disease of silkworm
<i>Nosema apis</i>	Bees	Spore	Ingestion	None	<i>Nosema</i> disease of bees
<i>Glugea hertwigi</i> <i>Glugea mulleri</i>	Various freshwater and marine fish	Spore	Ingestion	None	Microsporidiosis of fish
<i>Babesia caballi</i> <i>Babesia equi</i> (syn. <i>Theileria</i>)	Equines	Sporozoite	Tick bite	Various ticks (<i>Dermacentor</i> , <i>Hyalomma</i> , <i>Rhipicephalus</i> spp.)	Equine piroplasmosis

(continued)

Zoonoses, Table 1 (continued)

Parasite species	Principal hosts	Infective stage	Mode of infection	Other obligatory hosts	Disease
<i>Eimeria tenella</i>	Domestic poultry	Oocyst	Ingestion	None	Avian eimeriosis (coccidiosis)
<i>Eimeria averculina</i>					
<i>Eimeria bovis</i>	Bovines	Oocyst	Ingestion	None	Bovine eimeriosis (coccidiosis)
<i>Eimeria zürnii</i>					
<i>Theileria parva</i>	Cattle	Sporozoite	Tick bite	Ticks (<i>Rhipicephalus</i> spp.)	East Coast Fever
Trematodes					
<i>Fasciola gigantica</i>	Equines, bovines	Metacercaria	Ingestion	Aquatic snails	Fascioliasis
<i>Fascioloides magna</i>	Equines, bovines, sheep	Metacercaria	Ingestion	Aquatic snails (<i>Galba</i> , <i>Pseudosuccinea</i> , <i>Fossaria</i> spp.)	Fascioloidiasis
Nematodes					
<i>Ascaris suis</i>	Porcines	Egg containing 2nd-stage larva	Ingestion	None	Porcine ascariasis
<i>Parascaris equorum</i>	Equines	Egg containing 2nd-stage larva	Ingestion	None	Equine parascariasis
<i>Trichuris discolor</i>	Cattle	Embryonated egg	Ingestion	None	Bovine trichuriasis
<i>Trichuris suis</i>	Pigs	Embryonated egg	Ingestion	None	Porcine trichuriasis
Nematodes					
<i>Trichuris ovis</i>	Cattle, sheep	Embryonated egg	Ingestion	None	Trichuriasis of cattle and sheep
<i>Ancylostoma caninum</i>	Canines, felines	Strongyliiform larva	Transdermal penetration	None	Canine and feline ancylostomiasis
<i>Uncinaria stenocephala</i>					
<i>Strongyloides papillosus</i>	Sheep	Filariform larva	Transdermal penetration	None	Strongyloidosis of sheep
<i>Strongyloides ransomi</i>	Pigs	Filariform larva	Transdermal penetration	None	Strongyloidosis of pigs
<i>Dictyocaulus arnfieldi</i>	Equines	3rd-stage larva	Ingestion	None	Equine lungworm disease
<i>Trichostrongylus axei</i>	Cattle, sheep, horses	3rd-stage larva	Ingestion	None	Stomach worm disease
<i>Haemonchus contortus</i>	Sheep, other ruminants	3rd-stage larva	Ingestion	None	“Twisted” stomach worm disease

(continued)

Zoonoses, Table 1 (continued)

Parasite species	Principal hosts	Infective stage	Mode of infection	Other obligatory hosts	Disease
<i>Metastrongylus apri</i>	Mainly porcines	3rd-stage larva	Ingestion with earthworm	Earthworms (<i>Lumbricus</i> , <i>Eisenia</i> spp., etc.)	Swine lungworm disease
<i>Strongylus equines</i>	Equines	Strongyliform larva	Ingestion	None	<i>Strongylus</i> – disease of equines
<i>Protostrongylus rutescens</i>	Sheep, goats	3rd-stage larva	Ingestion with infected snail	Aquatic snails (mainly <i>Helicella</i> spp.)	Red lungworm disease
<i>Dirofilaria immitis</i>	Canines, felines	3rd-stage larva	Mosquito bite	<i>Culex</i> , <i>Aedes</i> , <i>Anopheles</i> spp.	Heartworm disease of dogs and cats

Zoonotic Disease Risk

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This term describes the behavioral, environmental, hygienic, economic, and other factors that influence the distribution of certain agents of disease, which have their origin in parasites in human surroundings.

Further Reading

Esatrada-Pena A (2014) Effects of environmental change on zoonotic disease risk: an ecological primer. Trends Parasitol 30:205–214

Zoonotic Trichomonads

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Besides the species ► *Dientamoeba fragilis*, ► *Pentatrichomonas hominis*, ► *Trichomonas vaginalis* and ► *T. tenax*, which are

defined human parasites, *D. fragilis* and *P. hominis* are found in addition inside domestic and farm animals and thus apparently are zoonotic parasites.

Further Reading

Hussein EM et al (2009) Genetic diversity of *Dientamoeba fragilis* isolates of irritated bowel syndrome patients. Parasitol Res 105:1053–1060

Zooparasites

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This term describes animals that live as parasites in or on animals.

Zoophagic

► **Mosquitoes** that exclusively bite animals.

Zygiella

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Genus of spiders characterized by a cross at the opisthosoma.

Zygote

Fusion product of gametes, ► [Syngamy](#).

Zygotokinete

More correct term for the ► [ookinete](#) of
 ► [Plasmodium](#) spp.

Zymodemes

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Name: *Greek: he zyme* = leaven, acts like yeast; *to demas* = body. Isoenzyme patterns of different strains of a parasite, e.g., ► [Entamoeba histolytica](#), ► [Amoebiasis](#). Bates and Ashford offer the following definition: “The group of strains (of a species) that share a given pattern of enzyme electrophoretic mobilities are known as a ‘zymodeme’”. A given species may contain a number of zymodemes indicating subpopulations or subspecies,” which apparently occur in *Entamoeba histolytica*, *Giardia lamblia*, *Leishmania* species, etc.

However, this method is not fully precise, since there is no standardization between international laboratories.
